

**IN THE UNITED STATES PATENT AND TRADEMARK OFFICE**  
**BEFORE THE BOARD OF PATENT APPEALS AND INTERFERENCES**

Applicants: T. KAJI, et al.  
Application No.: 10/808,559  
Filed: March 25, 2004  
For: A PLASMA PROCESSING APPARATUS  
Art Unit: 1763  
Examiner: A. Crowell **CONF. No. 4764**

***Notice of Appeal filed: June 12, 2007***

**APPELLANT'S BRIEF ON APPEAL**

**MS: BPAI**

Commissioner for Patents  
P.O. Box 1450  
Alexandria, VA 22313-1450

November 13, 2007

Sir:

In response to the Final Office Action mailed February 15, 2007, the present Appellants Brief is respectfully submitted under 37 CFR §41.37, in conjunction with the Appeal of the above-identified application. A timely Notice of Appeal was filed in this matter on June 12, 2007, together with a Petition for Extension of Time. A further Petition for Extension of Time is being filed herewith.

**I. Real Party of Interest**

The Real Party of Interest is Hitachi, Ltd. of Japan.

**II. Related Appeals and Interferences**

None.

**III. Status of Claims :**

Claims 8-25 and 27-38 are pending in this application. A copy of these claims which are on appeal appear in **Appendix A**.

**IV. Status of Amendments :**

The last amendment filed in this application was an Amendment After Final Rejection Pursuant to 37 CFR §1.116, filed on August 28, 2007 in response to the February 15, 2007 Final Office Action. Following the filing of the August 28, 2007 amendment, applicants received an Advisory Action mailed September 20, 2007, indicating that the August 28, 2007 Amendment would be entered for purposes of Appeal, but that the claims 8-25 and 27-38 remained rejected. No amendment has been filed since receipt of the September 20, 2007 Advisory Action.

**V. Summary of Claimed Subject Matter :**

The present invention is directed to an improved arrangement for a plasma processing apparatus for plasma processing of samples, such as semiconductor wafers, which samples include an insulator film.

Before discussing the claimed invention, a general introduction will be given to the invention by reference to the disclosure of the parent USP 6,197,151 (which is identical to the present application disclosure). A copy of the parent USP 6,197,151 is provided in **Appendix B**, and reference is made to this disclosure solely for purposes of convenience for the Board Members and the Examiner.

Referring first to Fig. 1, a vertical cross-sectional view of a first embodiment of the plasma etching apparatus of the present invention is shown. As discussed beginning on column 12, line 30 et seq., of the parent USP 6,197,151, a processing chamber 10 of a vacuum container is provided with a pair of opposed electrodes formed of an upper electrode 12 and a lower electrode 15. A sample 40 can be mounted on the lower electrode 15 for processing. A high-frequency power source 16 is provided to supply high-frequency energy to the upper electrode 12. As discussed on column 14, line 23 et seq., high-frequency electric power of between 30 Mhz. to 300 Mhz. can be provided by this high-frequency electric power source 16. On the other hand, the lower electrode 15 is connected to a pulse bias electric power source 17, as discussed on column 14, lines 30 et seq.

In order to provide gas to the processing chamber 10, a gas introducing chamber 34 is provided with a gas diffusion plate 32 for diffusing gas in a desired distribution (as discussed on column 12, line 58 et seq.). Holes 38 are provided in the upper electrode 12 in an upper electrode cover 30, formed over the upper electrode

12, to permit the gas to flow into the processing chamber 10. In addition, as an important feature of the invention, to be discussed in detail hereinafter :

"A discharge confining ring 37 is provided in the processing chamber 10 to increase plasma density and make the reaction inside the processing chamber uniform." (Column 13, lines 3-6).

As can also be seen in Fig. 1, this discharge confining ring 37 serves to separate the vacuum processing chamber 10 from an outer chamber. A small gap is included in the discharge confining ring to permit evacuating the processing gas from the vacuum processing chamber to the outer chamber.

The present invention is fundamentally directed to a problem noted, for example, in column 2, line 53 et seq., of the disclosure of the parent USP 6, 197,151.

Specifically:

"However, in the two-frequency exciting method or the MRIE method described above, it is difficult to stably produce a plasma having a desired density higher than  $5 \times 10^{10} \text{ cm}^{-3}$  under a pressure condition lower than 4 Pa."

In particular, in accordance with the present invention, as discussed above from column 13, line 3 et seq., the discharge confining ring 37 is particularly designed to permit increasing the plasma density and to make the reaction inside the processing chamber uniform. As will be discussed below, the material of the discharge confining ring, as well as the material of the electrode cover 30 and a susceptible cover 39 are all formed of material appropriate to minimize contamination within the plasma processing chamber. Accordingly, the following discussion regarding the claimed features all relates, in one way or another, to the three features of:

- 1) increasing plasma density within the vacuum processing chamber;
- 2) decreasing contamination within the vacuum processing chamber from the plasma etching process;

- 3) maintaining uniform reaction within the plasma processing chamber.

Turning to the claimed subject matter, each of the independent claims 8, 10, 19, 21, 27 and 28 defines at least the two features of the electrode cover being made of silicon and the discharge confining means being comprised of SiC defining or surrounding the vacuum processing chamber and including the function of "increasing plasma density in the plasma processing chamber." As such, each of the independent claims 8, 10, 19, 21, 27 and 28 define at least two of the above-noted features of designing the discharge confining means (and the electrode cover) to increase the plasma density within the vacuum processing chamber and to decrease contamination from etching.

More specifically, the discharge confining means defined in each of the independent claims can be read on the structure shown in Fig. 1 in which, with the exception of a small gap in the center of the discharge confining means, the discharge confining means completely encloses the vacuum processing chamber to produce an enclosed structure (together with the upper and lower electrodes) to permit the increasing of the plasma density within the vacuum processing chamber 10. As noted above, and discussed on column 2, line 53 et seq. and other places in the Specification, prior art structures have had problems with providing high plasma density, particularly at low pressures. As such, as discussed in column 13, line 3 et seq., the discharge confining means of the present invention is specifically defined to substantially completely enclose the vacuum processing chamber (with the exception of a small gap for evacuation) so that the plasma density can be increased to the desired level.

In addition, the electrode cover is made of silicon and the discharge confining means is comprised of SiC specifically to reduce contaminants which would otherwise occur if different materials, such as silica or quartz, such as found in a number of the references, were used. With regard to this, a Declaration by Dr. Shinichi Tachi is provided in the Evidence Appendix. This Declaration, which was submitted during the prosecution of the present application with the February 17, 2007 Amendment, discusses the importance of using materials which do not include Oxygen for forming the electrode cover, the susceptive cover and the discharge confining means in the present invention. In particular, as discussed by Dr. Tachi, the use of materials such as quartz or silica, found, for example, in a number of the cited references, including the primary reference to Lenz (USP 5,534,751) serve to release Oxygen into the plasma. This, as noted by Dr. Tachi, will degrade the etching results. Therefore, each of the independent claims specifically defines that the electrode cover is made of silicon and the discharge confining means is comprised of SiC so as to avoid this problem of contamination of the plasma.

A second feature of the present invention can be found in independent claims 8 and 10 and dependent claims 29-32. Specifically, these claims define that the discharge confining means not only defines or surrounds the vacuum processing chamber, but also serves to separate the vacuum processing chamber from the outer chamber, as shown in Fig. 1.

A third feature of the present invention, defined in claims 9, 10, 20, 21, 27 and 28-32 is that, in addition to the electrode cover being made of silicon, and the discharge confining means being comprised of SiC, the susceptive cover is also comprised of silicon. This susceptive cover, as shown by the numeral 39 in Fig. 1, is

also comprised of silicon to enhance the reduction of contamination from etching, as discussed above.

A fourth feature of the present invention as discussed above is that the discharge confining means is located to maintain a uniform reaction in the vacuum processing chamber. This is also discussed in column 13, lines 3-6. In particular, the particular structure of the discharge confining means to substantially completely surround and define the vacuum processing chamber serves to create this uniformity within the vacuum processing chamber. This feature is specifically defined by the dependent claims 33-38.

A fifth feature of the present invention, defined by the independent claim 28, is the specific feature of:

“means for generating a plasma with a density of  $5 \times 10^{10} \text{ cm}^{-3}$  to  $5 \times 10^{11} \text{ cm}^{-3}$  between said upper electrode and lower electrode to etch a fine pattern on the sample;”

This claimed feature operates in conjunction with the claimed discharge confining means which increases the plasma density within the vacuum processing chamber to achieve the plasma within the claimed range. This claimed range is quite important since, as discussed in column 2, lines 53 et seq., of the specification of the parent USP 6,197,151, prior art devices have failed to achieve this desired range of plasma density. This specific preferred range is discussed, for example, in column 14, line 46 et seq., as noted there, providing a plasma density within this range, in accordance with the present invention, particularly improves microworkability of a large diameter sample.

As a final sixth feature of the present claims, defined by independent claim 27, the present invention is particularly designed to generate a plasma to etch fine

patterns in samples with a diameter of 300 mm or larger. Column 3, lines 18 et seq., particularly note problems which have occurred in the etching of large diameter wafers of 300 mm or larger with prior art devices. By utilizing the specific claimed discharge confining means, it is possible to increase the plasma density to ensure sufficient plasma density and uniformity to properly etch such large diameter samples.

**VI. Grounds of Rejection To Be Reviewed On Appeal:**

Claims 8, 13, 16, 19, 24, 25, 29, 33 and 35 are rejected under 35 USC §103(a) as being unpatentable over Lenz et al (USP 5,534,751) in view of Ohmi (USP 5,272,417) and Lenz et al (USP 5,569,356).

Claims 9-12, 14-15, 17-18, 20-23, 30, 34 and 36 are rejected under 35 USC §103(a) as being unpatentable over Lenz et al (USP 5,534,751) in view of Ohmi (USP 5,272,417) and Lenz et al (USP 5,569,356) as applied to claims 8, 13, 16, 19, 24 and 25 above, and further in view of Steger et al (USP 5,494,523) or Ogasawara et al (JP 07-135200).

Claims 27, 28, 31, 32, 37 and 38 are rejected under 35 USC §103(a) as being unpatentable over Lenz et al (USP 5,534,751) in view of Ohmi (USP 5,272,417), Lenz et al (USP 5,569,356), Steger et al (USP 5,494,523) or Ogasawara et al (JP 07-135200) as applied to claims 9-12, 14-15, 17-18, and 20-23 above, and further in view of Koshiishi et al (USP 5,919,332) and Lenz et al (USP 5,609,720).

## **VII. ARGUMENTS**

As discussed above, each of the independent claims 8, 10, 19, 21, 27 and 28, together with the other listed claims 9, 20, 29-38 define one or more of the above-noted six features of the invention, as will be discussed below. The other dependent claims stand or fall with these listed claims.

Beginning with the rejection of independent claims 8 and 9 and their respective dependent claims over the combination of Lenz '751, Ohmi and Lenz '356, page 3 of the final Office Action relies on the Lenz '751 reference for teaching the claim limitations regarding a discharge confining means separating a vacuum chamber from an outer chamber "for increasing plasma density in the vacuum processing chamber." The rejection goes on to argue that, although Lenz fails to teach an electrode cover made of silicon, the Ohmi reference teaches such an electrode cover. Further, the final Office Action goes on to state that, although Lenz '751 fails to teach a discharge confining means made of SiC, the Lenz '356 reference does teach a discharge confining means 34 made of SiC.

In response, applicants respectfully submit that a close inspection of the Lenz '751 patent actually leads to the clear conclusion that this reference is not capable of meeting the claimed function of a discharge confining means for increasing the plasma density within the vacuum processing chamber. As an initial impression from Fig. 1 of the Lenz '751 patent, it would appear that it is similar to the discharge confining means 37 of Fig. 1 of the present application. However, Fig. 2 shows a much more accurate depiction of the confining assembly of the Lenz '751 patent which is comprised of a plurality of quartz circular rings 32 separated from one another by washers 34 to define a plurality of circumferential slots 31 "for which the

spent gasses within the inner action space 17 exit to flow out of the chamber 12.” Column 6, lines 33 and 34). In particular, from Fig. 2, it is quite clear that the circumferential slots 31 will comprise a very large area of the confinement ring 30.

Further, a careful reading of the purpose of the Lenz ‘751 patent leads to the conclusion that the term “confinement” as used in Lenz ‘751 is not meant in any way to physically confine the plasma to increase the plasma density, but, instead, to specifically structure the ring assembly so that particles exiting from the processing chamber will be neutralized so that the plasma does not extend outside of the ring assembly 30. This is quite clearly stated in column 2, lines 7 et seq., as follows:

“To this end, the present invention involves confining the plasma discharge to the inner action space between the electrodes by surrounding the inner action space with confining assembly defining a plurality of passages extending through the confinement assembly from an inner to an outer surface, the passages being proportioned to neutralize charge particles created in the plasma when the charge particles pass through the passages. ...In a typical embodiment, six rings were used to form five distinctive parallel circumferential slots therebetween in addition to the slots above and below. Moreover, the slots that are formed are appropriately proportioned such that the distance a charged gas particle from the plasma must travel in a slot in exiting it is substantially longer than the mean-free path of the particle so that most exiting particles make at least one collision with the walls of the slot. These collisions with the slot walls neutralize the charges on the particles and so the exiting particles are neutral. Accordingly, the tendency for a discharge outside the inner action space is essentially eliminated. “

In other words, the purpose of the Lenz ‘751 patent is specifically to define slots 31, acting with the rings 32, to prevent the plasma from being generated outside of the confinement area, not to increase the plasma density within the confinement area, as required by the present means-plus-function claim language.

Viewing Fig. 2 of the Lenz ‘751 patent makes it very clear that the slots 31 represent such a large portion of the confinement ring structure 30, that a very substantial particle flow will exist which would effectively prevent increasing plasma density

within the confinement region. Further, absolutely nothing in Lenz '751 at all suggests that it was intended to actually increase plasma density with this structure. Instead, the goal of Lenz is to neutralize particles that escape from the confinement chamber so that they are neutralized once they leave this confinement chamber. Therefore, the fundamental feature of each of the independent claims 8 and 19, rejected in the first ground of rejection of means for increasing the plasma density in the vacuum processing chamber is lacking from the Lenz '751 structure.

In addition, as recognized in the Office Action, Lenz '751 fails to teach the use of SiC for the discharge confining means. Instead, it is very clearly stated at several locations throughout the Lenz patent that silica or quartz rings are used. This is discussed in the first line of the Abstract, for example. (Column 6, line 16 et seq., clearly states that the stack of circular rings is formed of "a dielectric that preferably is high quality fused silica or quartz." A number of the Lenz claims also specifically define the formation with dielectric material or quartz. As such, the primary reference of Lenz '751 will suffer from the specific problem of oxygen degradation of the plasma noted by Dr. Tachi's Declaration found in the Evidence Appendix.

The Office Action refers to Lenz '356 as teaching a discharge confining means 34 made of SiC. With regard to this, applicants respectfully submit that the fact that Lenz '751 and Lenz '356 have the same lead inventor (i.e., Lenz), and that the Lenz '356 was actually filed on May 19, 1995, before the July 10, 1995 filing date of the application leading to the '751 patent, clearly if Lenz had any intention of utilizing SiC as the discharge ring material in the '751 patent, this would have been disclosed as an alternative. It is urged that the fact that the Lenz '751 patent is completely devoid of any suggestion of SiC leads to the conclusion that Lenz

regarded SiC as inappropriate for his discharge ring 30. This is not at all surprising given the fact that the discharge confining ring 30 taught by Lenz '751 has a very specific purpose of neutralizing charges by particles escaping through its numerous slots 31. Evidentially, the use of "highly fused silica or quartz" (column 6, line 18) was an important requirement for the ring structure of the '751 patent. Therefore, it is respectfully submitted that the failure of Lenz to disclose SiC as an alternative in the '751 patent leads to a clear teaching away from the modification of the Lenz '751 structure in this manner. And, in any event, even if one were to use SiC in the Lenz '751 structure, the end result would still be completely different from the claimed discharge confinement means since, as noted above, the ring structure of the '751 patent is incapable of meeting the claim limitation of means for increasing plasma density within the vacuum processing chamber.

Turning to the rejection of claims 9-12, 14, 15, 17-18, 20-23, 30, 34 and 36 over the same references of Lenz '751 in view of Ohmi and Lenz '356, together with Steger and Ogasawara, it is noted, firstly, that Steger and Ogasawara add absolutely nothing to the other three cited references to overcome the shortcomings of these references noted above. It is also noted that each of the other independent claims 10, 21, 27 and 28 define the same features noted above for independent claims 8 and 19 in defining over the combination of Lenz '751, Ohmi and Lenz '356.

Turning to this specific rejection, Steger and Ogasawara are both cited for teaching a susceptible cover comprised of silicon. Although these references are of general interest concerning susceptible covers, the fact remains that the rejected claims define an overall combination of elements which include an electrode cover and a susceptible cover of silicon, together with a discharge confinement means

comprised of SiC for increasing plasma density within a vacuum processing chamber. Even if the reference to Lenz '751 were modified to include the susceptible covers of Steger and Ogasawara, the combination would still not include a discharge confinement means comprised of SiC to increase plasma density within a vacuum processing chamber. Therefore, reconsideration and removal of this rejection is also respectfully requested.

Turning next to the rejection of claims 27, 28, 31, 32, 37 and 38 over the Lenz '751 patent, Ohmi, Lenz '356, Steger, Ogasawara and further in view of Koshiishi and Lenz '720, the Koshiishi patent is cited to teach the claimed plasma density range between  $5 \times 10^{10} \text{cm}^{-3}$  to  $5 \times 10^{11} \text{cm}^{-3}$ . Lenz '720 is cited with regard to processing of chambers having a diameter of 300 mm. Regarding this, it is again noted that nothing in either Koshiishi or Lenz '720 overcomes the fundamental failings of the other references to meet the claim limitations concerning the discharge confining means comprised of SiC for increasing plasma density within the vacuum processing chamber.

With particular regard to the feature of the plasma density being in the claimed range (as defined in claim 28), as noted above, this claimed range is important in the present invention because it is a plasma density range which was not achieved by prior art structures, particularly at low plasma densities. With regard to the distinctions over Koshiishi, it is noted that the present claims are specifically directed to the discharge confining means being comprised of SiC for increasing plasma density in the plasma processing chamber to achieve this claimed range. It is respectfully submitted that nothing in Koshiishi suggests the structuring of the discharge confining means, comprised of SiC, to achieve this particular result.

Further, it would take a complete restructuring of the primary Lenz '751 ring structure 30, with its numerous slots 31, to be able to achieve the claimed increase in plasma density to arrive at this claimed range. Koshiishi's only teachings concerning any plasma confinement structure are the formation of the upper electrode 31 "of transparent quartz or the like" (column 14, line 18). As defined in column 12, line 41 et seq., this upper insulating member 31 is used to prevent the plasma from being directly diffused towards inner walls of the processing container 3. However, absolutely nothing in Koshiishi suggests that the upper insulator 31 would serve to meet the limitation of a discharge confining means for increasing plasma density within the processing chamber. Also, given the fact that it covers only the upper half of the vacuum processing chamber, obviously there is completely insufficient coverage to increase the plasma pressure within the processing chamber, as required by the present means-plus-function claim language found in each of the independent claims 8, 10, 19, 21, 27 and 28. Therefore, it is respectfully submitted that the combination of the plasma density and the discharge confining means for increasing plasma density set forth in claim 28 is neither taught nor suggested by the combination relying on Koshiishi set forth in the rejection.

As for the Lenz '720 patent, although this teaches the use of processing wafers of 300 mm or larger, nothing in this reference suggest the claim discharge confining means for increasing plasma density within the vacuum processing chamber. As discussed above, large wafers of 300 mm or more suffer from particular problems of uniformity due to their large size. independent claim 27 is specifically directed to the combination of the claimed discharge confining means and the ability of the claimed invention to etch fine patterns on wafers of 300 mm or

larger. Again, there is nothing in the Lenz '720 patent which suggests the particular design of a discharge confining means to achieve the sufficient pressure and uniform etching of such a large diameter wafer. Therefore, also Lenz '720 operates on wafers of 300 mm or larger, again, there is nothing to suggest the complete modification of Lenz '751 which would be necessary to modify that structure to operate as a discharge confining means for increasing plasma density within a vacuum processing chamber.

The above discussion pertains to all of the six features originally discussed in the preceding section of the claimed subject matter except for the two features of the discharge confining means separating the vacuum processing chamber from the outer chamber (claims 8, 10 and 29-32) and a discharge confining means being located to maintain uniform reaction in the vacuum processing chamber (dependent claim 33 – 38). With regard to this, although the Lenz '751 patent has been cited for teaching separation of a vacuum processing chamber from an outer chamber, it is noted that this "separation" is by a ring structure which is very largely comprised of slots 31 which will significantly reduce any effective separation of the vacuum processing chamber from the outer chamber. Again, the concept of Lenz '751 is not to confine the plasma physically within the vacuum processing chamber (by the separation achieved in the present claimed invention), but, instead, to neutralize the many escaping particles from the vacuum processing chamber to the outer chamber. Therefore, it is respectfully submitted that the claimed combination of elements will not teach or suggest the claimed discharge confining means separating a vacuuming processing chamber from an outer chamber.

Similarly, it is respectfully submitted that nothing in the cited prior art teaches the features defined by dependent claims 33-38 of locating a discharge confining means which increases the plasma density and maintains uniform reactions in the vacuum processing chamber. Concerning this feature, the final Office Action states on page 5, lines 9 et seq., that:

“With respect to claims 33 and 35, the apparatus of Lenz et al further wherein the discharge confining means 30 is located for maintaining a uniform reaction in the vacuum processing chamber (column 3, lines 23-28).”

It is assumed that the Lenz et al being referred to Lenz '751. Column 3, lines 23-28 of Lenz '751 states:

“Viewed from another aspect, the present invention is directed to plasma etching apparatus that includes plasma confinement. The plasma etching apparatus comprises means for housing a gaseous medium useful for etching, a parallel pair of electrodes, and a stack of at least three spaced-apart rings.”

It is respectfully submitted that absolutely nothing in this language from the Lenz '751 teaches or suggests the claimed feature of “the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.” Indeed, absolutely nothing is found in this quoted section concerning uniform reactions at all. As noted above, the term “plasma confinement” in Lenz '751 apparently relates to neutralizing charged particles as they exit through the “spaced apart rings” referred to in column 3, lines 23-28. This apparent large escape of particles certainly would not pertain to either increasing plasma density or maintaining a uniform reaction in the vacuum processing chamber. The structure of Lenz '751 is simply very different from the structure defined by the present discharge confining means. Therefore, particular consideration of these claims 33-38 is also respectfully requested.

**VIII. Conclusion:**

For the foregoing reasons, appellants request that the Examiner's rejections be reversed.

If the Examiner believes that there are any other points which may be clarified or otherwise disposed of either by telephone discussion or by personal interview, the Examiner is invited to contact Applicants' undersigned attorney at the number indicated below.

An electronic payment covering the Appeal Brief filing fee of \$510.00 is being submitted concurrently herewith.

To the extent necessary, Applicants petition for an extension of time under 37 CFR 1.136. Please charge any shortage in fees due in connection with the filing of this paper, including extension of time fees, to the Antonelli, Terry, Stout & Kraus, LLP Deposit Account No. 01-2135 (Docket No. 520.35237CV4), and please credit any excess fees to such deposit account.

Respectfully submitted,

## APPENDIX A

1. – 7. (Canceled)

8. A plasma processing apparatus comprising:

- a vacuum processing chamber for processing a sample, including an insulator film, by using plasma;
- an outer chamber surrounding the vacuum processing chamber connected with an evacuation means;
- a gas supplying unit for introducing into the vacuum processing chamber a fluorine-containing processing gas;
- an upper electrode and a lower electrode for generating plasma therebetween and providing the vacuum processing chamber;
- an electrode cover made of silicon being provided at the outer surface of the upper electrode; and
- a discharge confining means comprised of SiC for separating the vacuum processing chamber from the outer chamber and for increasing plasma density in the vacuum processing chamber .

9. The plasma processing apparatus according to claim 8; the lower electrode having a sample mounting surface; said apparatus further comprising a susceptible cover comprised of silicon near the sample mounting surface.

10. A plasma processing apparatus comprising:

a vacuum processing chamber for processing a sample, including an insulator film, by using plasma;

a gas supplying unit for introducing into the vacuum processing chamber a fluorine-containing processing gas;

an upper electrode and a lower electrode for providing the vacuum processing chamber therebetween;

an outer chamber surrounding the vacuum processing chamber and connected with an evacuation means;

a high frequency electric power source for supplying a high frequency energy for generating plasma between the upper electrode and the lower electrode;

a bias electric power source connected to the lower electrode to control energy of ions in the plasma;

an electrode cover comprised of silicon being provided at the outer surface of the upper electrode;

a susceptive cover comprised of silicon being provided near a sample mounting surface of the lower electrode; and

a discharge confining means comprised of SiC for separating the vacuum processing chamber from the outer chamber and for increasing plasma density in the vacuum processing chamber .

**Claim 11. (Canceled)**

12. The plasma processing apparatus according to claim 10, wherein the discharge confining means includes at least a gap for evacuating the processing gas from the vacuum processing chamber to the outer chamber.

13. The plasma processing apparatus according to claim 8, wherein the discharge confining means is ring-shaped.

14. The plasma processing apparatus according to claim 9, wherein the discharge confining means is ring-shaped.

15. The plasma processing apparatus according to claim 10, wherein the discharge confining means is ring-shaped.

16. The plasma processing apparatus according to claim 8, wherein the discharge confining means is provided with at least a gap for evacuating the processing gas from the vacuum processing chamber to the outer chamber.

17. The plasma processing apparatus according to claim 9, wherein the discharge confining means is provided with at least a gap for evacuating the processing gas from the vacuum processing chamber to the outer chamber.

18. The plasma processing apparatus according to claim 13, wherein the discharge confining means is provided with at least a gap for evacuating the processing gas from the vacuum processing chamber to the outer chamber.

19. A plasma processing apparatus comprising:

a vacuum container for processing a sample including an insulator film by use of plasma;

a gas supplying unit for introducing into the vacuum container a processing gas containing fluorine;

an upper electrode and lower electrode having plasma generated therebetween;

an electrode cover made of silicon provided at the bottom surface of the upper electrode; and

a discharge confining means comprised of SiC for defining a surrounding vacuum processing chamber in the vacuum container in the space between said upper and lower electrodes and for increasing plasma density in the vacuum processing chamber.

20. The plasma processing apparatus according to claim 19:

wherein said lower electrode includes a sample mounting surface, and further comprising a susceptible cover around the sample mounting surface, and wherein said susceptible cover is also made of silicon.

21. A plasma processing apparatus comprising:

a vacuum container for processing of a sample including an insulator film through the use of plasma;

a gas supplying unit for introducing into the vacuum container a processing gas containing fluorine;

an upper electrode and lower electrode for defining a vacuum processing chamber therebetween;

a high frequency electric power source for supplying a high frequency energy for generating plasma in the vacuum processing chamber;

a bias electric power source connected to the lower electrode to control the energy of ions in the plasma;

an electrode cover made of silicon being provided at the bottom surface of the upper electrode;

a susceptive cover made of silicon provided around a sample mounting surface of the lower electrode; and

a discharge confining means made of SiC for surrounding the vacuum processing chamber in the vacuum container and for increasing plasma density in the vacuum processing chamber.

22. The plasma processing apparatus according to claim 21 further comprising an outer chamber defined within the vacuum container outside of the vacuum processing chamber, said outer chamber being connected with an evacuation means.

23. The plasma processing apparatus according to claim 21 wherein the discharge confining means includes at least a gap for evacuating the processing gas from the vacuum processing chamber to the outer chamber.

24. The plasma processing apparatus as in claim 19 wherein the discharge confining means is ring shaped.

25. The plasma processing apparatus according to claim 19 and further comprising an outer chamber defined in said vacuum container outside of said vacuum processing chamber and wherein the discharge confining means is provided with at least a gap for evacuating the processing gas from the vacuum processing chamber to the outer chamber.

**Claim 26. (Canceled)**

27. A plasma etching apparatus comprising:

a vacuum container for processing a sample including an insulator film by use of plasma;

an upper electrode and lower electrode having plasma generated therebetween;

wherein said plasma etching apparatus further comprises:

a gas supplying unit for introducing into the vacuum container a processing gas containing fluorine;

means for generating a plasma between said upper electrode and lower electrode to etch a fine pattern on the sample having a diameter of 300 mm or more;

a bias electric power source connected to the lower electrode to control energy of ions in said plasma;

a discharge confining means comprised of SiC for defining a vacuum processing chamber in the space between said upper and lower electrodes in the vacuum container and for increasing plasma density in the vacuum processing chamber;

an electrode cover provided at the bottom surface of the upper electrode, wherein the electrode cover is made of silicon and includes holes to pass the processing gas;

a susceptive cover, made of silicon, provided around a sample mounting surface of the lower electrode.

28. A plasma etching apparatus comprising:

a vacuum container for processing a sample including an insulator film by use of plasma;

an upper electrode and lower electrode having plasma generated therebetween;

wherein said plasma etching apparatus further comprises:

a gas supplying unit for introducing into the vacuum container a processing gas containing fluorine;

means for generating a plasma with a density of  $5 \times 10^{10} \text{ cm}^{-3}$  to  $5 \times 10^{11} \text{ cm}^{-3}$  between said upper electrode and lower electrode to etch a fine pattern on the sample ;

a bias electric power source connected to the lower electrode to control energy of ions in said plasma;

a discharge confining means comprised of SiC for defining a vacuum processing chamber in the space between said upper and lower electrodes and for increasing plasma density in the vacuum processing chamber;

an electrode cover provided at the bottom surface of the upper electrode, wherein the electrode cover is made of silicon and includes hole to pass the processing gas; and

a susceptible cover made of silicon provided around the sample mounting surface of the lower electrode.

29. A plasma processing apparatus according to claim 19, wherein the vacuum container includes an outer chamber, connected with an evacuation means, surrounding the vacuum processing chamber, and wherein the discharge confining means is located to serve as means for separating the vacuum processing chamber from the outer chamber.

30. A plasma processing apparatus according to claim 21, wherein the vacuum container includes an outer chamber, connected with an evacuation means, surrounding the vacuum processing chamber, and wherein the discharge confining means is located to serve as means for separating the vacuum processing chamber from the outer chamber.

31. A plasma etching apparatus according to claim 27, wherein the vacuum container includes an outer chamber, connected with an evacuation means, surrounding the vacuum processing chamber, and wherein the discharge confining

means is located to serve as means for separating the vacuum processing chamber from the outer chamber.

32. A plasma etching apparatus according to claim 28, wherein the vacuum container includes an outer chamber, connected with an evacuation means, surrounding the vacuum processing chamber, and wherein the discharge confining means is located to serve as means for separating the vacuum processing chamber from the outer chamber.

33. A plasma processing apparatus according to claim 8, wherein the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.

34. A plasma processing apparatus according to claim 10, wherein the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.

35. A plasma processing apparatus according to claim 29, wherein the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.

36. A plasma processing apparatus according to claim 30, wherein the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.

37. A plasma etching apparatus according to claim 31, wherein the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.

38. A plasma etching apparatus according to claim 32, wherein the discharge confining means is located for maintaining a uniform reaction in the vacuum processing chamber.

(57) **ABSTRACT**

A plasma processing apparatus comprising a vacuum processing chamber, a plasma generating means including a pair of electrodes, a sample table for mounting a sample to be processed inside the vacuum processing chamber and also serving as one of the electrodes, and a evacuating means for evacuating the vacuum processing chamber, which further comprises a high frequency electric power source for applying an electric power of a VHF band from 50 MHz to 200 MHz between the pair of electrodes; and a magnetic field forming means for forming a static magnetic field or a low frequency magnetic field larger than 10 gauss and smaller than 110 gauss in a direction intersecting an electric field generated between the pair of electrodes and the vicinity by the high frequency electric power source; therein the magnetic field forming means being set so that a portion where a component of the magnetic field in a direction along the surface of the sample table becomes maximum is brought to a position in the opposite side of the sample table from the middle of the both electrodes; an electron cyclotron resonance region being formed between the both electrodes by the magnetic field and the electric field.

Further, in regard to an example of utilizing cyclotron resonance of the VHF band, installation of a bias electric power source for applying a voltage to a sample table and a means for uniformly applying a voltage all over a sample surface are described in Journal of Applied Physics, Japan, Vol.28, No. 10. Further, a processing chamber has a height higher-than 200 mm. Therefore, the construction cannot use

5.

In regard to the frequency  $f$  of the high frequency electric power source, by employing VHF in the range  $50 \text{ MHz} \leq f \leq 200 \text{ MHz}$  the plasma density is decreased by one order to two orders compared to that in a case of a microwave ECR. The dissociation of gas is also decreased and accordingly generation of unnecessary fluorine atoms and/or molecules and ions are also decreased by one order or more. By using the frequency in the VHF band and the cyclotron resonance, it is possible to obtain a plasma having an appropriately high density and a high processing rate under a pressure condition of 0.4 Pa to 4 Pa. Further, since the

dissociation of processing gas is not excessively progressed, the selectivity to the base material such as Si, SiN or the like is not significantly degraded.

Although the dissociation of processing gas only progresses slightly compared to that in a conventional apparatus of the parallel flat plate electrode type using a frequency of 13.56 MHz, the disadvantage of the small increase in the amount of fluorine atoms and/or molecules and/or ions can be eliminated by providing a material containing silicon or carbon on the surface of the electrodes and/or a wall surface of the chamber, and further by applying a bias voltage to the electrodes and the chamber or by exhausting fluorine through coupling the fluorine with hydrogen using a gas containing hydrogen atom.

Further, according to the present invention, a portion where the component of the magnetic field parallel to the sample table between the electrodes is set at a position on the side opposite to the sample table from the middle of both electrodes and the magnetic field intensity on the surface of the sample table mounting the sample parallel to the sample table is set below 30 gauss, preferably, below 15 gauss. Thereby, a Lorentz force ( $E \times B$ ) acting on electrons near the sample mounting surface is made small, and consequently occurrence of non-uniformity by the electron drift effect due to the Lorentz force on the sample mounting surface can be eliminated.

The present invention is characterized by the fact that the cyclotron resonance effect of electrons is larger in a portion within a range from the periphery of a sample to the outer side of the periphery than in the center of the sample so as to increase the generation of plasma in the portion within the range from the periphery of the sample to the outer side of the periphery than in the center of the sample. A means for decreasing the effect of the cyclotron resonance of electrons can be attained by increasing the distance between the cyclotron resonance region and the sample, or decreasing the degree of intersection between the magnetic field and the electric field.

When a gradient of the magnetic field near the cyclotron resonance region  $B_c$  is steepened to narrow the ECR resonance region, the cyclotron effect can be weakened. The ECR resonance region is formed in a range of a magnetic field intensity  $B$ ,  $B_c(1-a) \leq B \leq B_c(1+a)$  where  $0.05 \leq a \leq 0.1$ .

A large amount of ions are generated in the ECR resonance region since dissociation of the processing gas progresses there. On the other hand, a large amount of radicals are generated in the region other than the ECR resonance region since the dissociation of the processing gas does not progress significantly compared to progression in the ECR resonance region. By adjusting a width of the ECR resonance region and a high frequency electric power applied to the upper electrode, it is possible to independently control the amount of generated ions and the amount of generated radicals appropriate for processing the sample.

The present invention is characterized by a plasma processing apparatus comprising a vacuum processing chamber, a sample table for mounting a sample to be processed in the vacuum processing chamber, and a plasma generating means including a high frequency electric power source, which further comprises an electrostatic attracting means for holding the sample onto the sample table by an electrostatic attracting force; and a pulse bias applying means for applying a pulse bias voltage to the sample; the high frequency electric power source applying a high frequency voltage of 10 MHz to 500 MHz, the vacuum processing chamber being depressurized to 0.5 to 4.0 Pa.

The present invention is further characterized by a plasma processing apparatus comprising a vacuum processing chamber, a sample table for mounting a sample to be processed in the vacuum processing chamber, and a plasma generating means including a high frequency electric power source, which further comprises an electrostatic attracting means for holding said sample onto the sample table by an electrostatic attracting force; a pulse bias applying means connected to the sample table and for applying a pulse bias voltage to the sample; and a voltage suppressing means for suppressing a voltage rise generated by applying a pulse bias voltage corresponding to an electrostatic attracting capacity of the electrostatic attracting means.

The present invention is also characterized by a method of plasma processing comprising the steps of placing a sample on one of a pair of electrodes opposite to each other provided in a vacuum processing chamber; holding the sample onto the electrode by an electrostatic attracting force; introducing an etching gas into an environment in which the sample is placed; evacuating the environment to a pressure condition of 0.5 Pa to 4.0 Pa; forming the etching gas into a plasma under the pressure condition by applying a high frequency electric power of 10 MHz to 500 MHz; etching the sample by the plasma; and applying a pulse bias voltage to the one of the pair of electrodes.

The present invention is further characterized by a method of plasma processing comprising the steps of placing a sample on one of the electrodes opposite to each other; holding the placed sample onto the electrode by an electrostatic attracting force; introducing an etching gas into an environment in which the sample is placed; forming the introduced etching gas into a plasma; etching the sample by the plasma; and applying a pulse bias voltage having a pulse width of 250 V to 1000 V and a duty ratio of 0.05 to 0.4 to the one of electrodes during etching, whereby an insulator film, such as  $SiO_2$ , SiN, BPSG or the like, in the sample is plasma-processed.

According to another characteristic of the present invention, by applying a pulse-shaped bias voltage having a proper characteristic to a sample table having an electrostatic attracting means with a dielectric layer for electrostatic attracting, it is possible to appropriately control the temperature of a sample and stably perform required fine pattern processing. That is, the plasma processing apparatus comprises an electrostatic attracting means for holding a sample onto a sample table by an electrostatic attracting force, and a pulse bias applying means connected to the sample table for applying a pulse bias voltage to the sample table. The pulse bias voltage has a period of 0.2 to 2  $\mu$ s and a duty cycle in the positive direction less than one-half, and is applied to the sample through a capacitance element.

According to a further characteristic of the present invention, in regard to a voltage suppressing means for suppressing change in a voltage generated by applying the pulse bias voltage corresponding to an electrostatic attracting capacity of the electrostatic attracting means, the voltage suppressing means is designed so that voltage change due to an electrostatic attracting film of the electrostatic attracting means during one cycle of pulse is suppressed to one-half of the pulse bias voltage. In detail, this can be attained by reducing a thickness of an electrostatic chuck film made of a dielectric material provided on the surface of the lower electrode, or by employing a material having a large specific dielectric coefficient. Further, it is also possible to employ a method of suppressing an increase of voltage applied to both ends of the dielectric layer by shortening the period of the pulse bias voltage.

According to a further characteristic of the present invention, by applying a pulse bias voltage having a pulse width of 250 V to 1000 V and a duty ratio of 0.05 to 0.4 to the one of electrodes during etching, it is possible to improve the plasma processing selectivity of the base material of an insulator film, such as  $\text{SiO}_2$ ,  $\text{SiN}$ , BPSG or the like.

The present invention is characterized by a plasma processing apparatus comprising a vacuum processing chamber, a sample table for mounting a sample to be processed in the vacuum processing chamber, and a plasma generating means, which further comprises an electrostatic attracting means for holding the sample onto the sample table by an electrostatic attracting force; a bias applying means for applying a bias voltage to the sample; a radical supplying means having a means decomposing a gas for generating radicals in advance and for supplying a required amount of the radicals to the vacuum processing chamber; a means for supplying a gas for generating ions to the vacuum processing chamber; and a plasma generating means for generating a plasma in the vacuum processing chamber, wherein  $\text{SiO}_2$  is used as the sample.

The present invention is further characterized by a plasma processing apparatus comprising a vacuum processing chamber, a sample table for mounting a sample to be processed in the vacuum processing chamber, and a plasma generating means including a high frequency electric power source, which further comprises an electrostatic attracting means for holding the sample onto the sample table by an electrostatic attracting force; a pulse bias applying means for applying a pulse bias voltage to the sample; a radical generating plasma supplying means for forming a gas for generating radicals into a plasma in advance and for supplying a required amount of the radicals to the vacuum processing chamber; and the plasma generating means for supplying a gas for generating ions to the vacuum processing chamber and for generating a plasma in the vacuum processing chamber, whereby the high frequency electric power source applying a high frequency voltage of 10 MHz to 500 MHz, the vacuum processing chamber can be depressurized to 0.5 to 4.0 Pa.

According to another characteristic of the present invention, by controlling the amounts and the qualities of ions and radicals independently and applying a pulse bias voltage having an appropriate characteristic to a sample table having an electrostatic attracting means with a dielectric layer for electrostatic attracting, it is possible to properly control temperature of a sample and to stably perform required fine pattern processing.

Further, it is possible to improve the selectivity of plasma processing with a stable and better control condition by controlling the amounts and the qualities of ions and radicals independently and by obtaining a narrow ion energy distribution.

Furthermore, the amounts and the qualities of ions and radicals are independently controlled, and a voltage suppressing means, which suppresses change in a voltage corresponding to an electrostatic attracting capacity of the electrostatic attracting means generated by applying the pulse bias voltage, is designed so that voltage change due to an electrostatic attracting film of the electrostatic attracting means during one cycle of pulse is suppressed to one-half of the pulse bias voltage. In detail, this can be attained by reducing a thickness of an electrostatic chuck film made of a dielectric material provided on the surface of the lower electrode, or by employing a material having a large specific dielectric coefficient. Further, it is also possible to employ a

method of suppressing an increase of voltage applied to both ends of the dielectric layer by shortening the period of the pulse bias voltage.

According to a further characteristic of the present invention, since the amounts and the qualities of ions and radicals are independently controlled and a pulse bias voltage having a pulse width of 250 V to 1000 V and a duty ratio of 0.05 to 0.4 is applied to the one of electrodes during etching, it is possible to improve the plasma processing selectivity of the base material to an insulator film, such as  $\text{SiO}_2$ ,  $\text{SiN}$ , BPSG or the like.

Further according to a characteristic of the present invention, the amounts and the qualities of ions and radicals are independently controlled, a high frequency electric power source for generating a plasma of a high frequency voltage of 10 MHz to 500 MHz is used, and gas pressure in the processing chamber is set to a low pressure of 0.5 Pa to 4.0 Pa. Thereby, it is possible to obtain a stable plasma. Further, by using such a high frequency voltage, the plasma is well ionized and the control of selectivity during processing a sample is improved.

#### BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a vertical cross-sectional view showing an embodiment of a plasma etching apparatus of a two-electrode type in accordance with the present invention.

FIG. 2 is a graph showing an example of change in plasma density when the frequency of a high frequency electric power source for generating a plasma is changed under a condition where a magnetic field for producing cyclotron resonance of electrons is applied.

FIG. 3 is a graph showing energy gains  $k$  of electrons obtained from a high frequency electric field under conditions with and without cyclotron resonance.

FIG. 4 is a graph showing the relationship between intensity of a magnetic field and an ion acceleration voltage  $V_{DC}$  induced in a sample, as well as the deviation  $\Delta V$  of an induced voltage in the sample when an upper electrode of a magnetron discharge electrode is grounded and a lower electrode is applied with a magnetic field  $B$  and a high frequency electric power.

FIG. 40 is a vertical cross-sectional view showing a further embodiment of a plasma etching apparatus of a two-electrode type in accordance with the present invention.

#### DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Embodiments of the present invention will be described below. FIG. 1 shows a first embodiment of a plasma etching apparatus using opposed electrodes to which the present invention is applied.

Referring to FIG. 1, a processing chamber 10 of a vacuum container has a pair of opposed electrodes composed of an upper electrode 12 and a lower electrode 15. On the lower electrode 15 a sample 40 is mounted. The distance of a gap between the electrodes 12 and 15 is preferably not smaller than 30 mm in order to suppress a pressure difference on the sample to within 10% when the sample has a large diameter of about 300 mm or larger. In order to decrease amounts of fluorine atoms, molecules and ions, the distance is desired to be not larger than 100 mm, preferably, not larger than 60 mm from the view point of effectively using a reaction product on the surfaces of the upper and the lower electrodes. A high frequency electric power source 16 for supplying a high frequency energy is connected to the upper electrode 12 through a matching box 162. The reference character 161 indicates a high frequency electric power modulating signal source. Between the upper electrode 12 and the ground there is connected a filter 165 which becomes a low impedance to the frequency component of a bias electric power source 17 and becomes a high impedance to the frequency component of the 15S high frequency electric power source 16. The reference character 13 indicates an insulator member made of aluminum oxide or the like.

The area of the upper electrode 12 arranged nearly parallel to the sample table is larger than an area of the sample 40 to be processed so that voltage of the bias electric power source 17 is effectively and uniformly applied to the sheath on the sample table.

An upper electrode cover 30 of a fluorine removing plate made of silicon, carbon or SiC is provided on the bottom surface of the upper electrode 12. Further, a gas introducing chamber 34 is provided having a gas diffusion plate 32 for diffusing gas in a desired distribution. A gas necessary for processing operations such as etching the sample is supplied to the processing chamber 10 from a gas supplying unit 36 through the gas diffusion plate 32 of the gas introducing chamber 34, and holes 38 are provided in the in the upper electrode 12 and the upper electrode cover 30. An outer

13

chamber 11 is evacuated by a vacuum pump 18 connected to the outer chamber 11 through a valve 14 to adjust pressure in the processing chamber 10 to a process pressure. A discharge confining ring 37 is provided in the processing chamber 10 to increase plasma density and make the reaction inside the processing chamber uniform. The discharge confining ring 37 has gaps for evacuation.

Above the upper electrode 12, there is provided a magnetic field forming means 200 which forms a magnetic field intersecting with an electric field E formed between the electrodes at a right angle and parallel to the surface of the sample 40. The magnetic field forming means 200 has a core 201, an electromagnetic coil 202 and an insulator member 203. A material for constructing the upper electrode 12 is a non-magnetic conductor such as aluminum, an aluminum alloy or the like. A material for constructing the processing chamber 10 is a non-magnetic material such as aluminum, an aluminum alloy, aluminum oxide, quartz, SiC or the like. The core 201 is formed in an axial-rotating symmetrical structure having a nearly E-shaped cross section with the cores 201A, 201B so as to form a magnetic field B of which the magnetic fluxes extend from the upper central portion of the processing chamber 10 toward the upper electrode 12 and then extend along and in parallel to the upper electrode 12 toward the periphery of the upper electrode. The magnetic field formed between both electrodes by the magnetic field forming means 200 has a portion of a static magnetic field or a low frequency magnetic field (lower than 1 kHz) having an intensity of 10 gauss to 110 gauss, preferably, 17 gauss to 72 gauss for producing cyclotron resonance.

It is well-known that the relationship between an intensity  $B_c$  (gauss) of the magnetic field for producing cyclotron resonance and a frequency  $f$  (MHz) of the plasma forming high frequency source can be expressed as  $B_c = 0.357 \times f$  (MHz).

The two electrodes 12 and 15 in the present structure may have some indent portions or projecting portions depending on, for example, a requirement of a plasma forming characteristic as far as the pair of opposite electrodes 12 and 15 are substantially in parallel to each other. In such a two-electrode type, the electric field distribution between the two electrodes can be easily made uniform. Accordingly, generation of plasma by cyclotron resonance can be made uniform comparatively easily by improving the uniformity of the magnetic field intersecting with the electric field at a right angle.

The lower electrode 15 mounting and holding the sample 40 has a two-pole type electrostatic chuck 20. That is, the lower electrode 15 is composed of a first lower electrode 15A in the outer side and a second lower electrode 15B arranged in the inner side through an insulator member 21, and an electrostatic attracting dielectric layer 22 (hereinafter referred to as an electrostatic attracting film) is provided on the upper surfaces of the first and the second lower electrodes. A direct current source 23 is connected to the first and second lower electrodes through coils 24A, 24B for cutting a high frequency component to apply a direct current voltage between both lower electrodes so that the second lower electrode 15B is charged positively. Thereby, the sample 40 is attracted and held onto the lower electrode 15 by a Coulomb force acting between the sample 40 and both lower electrodes through the electrostatic attracting film 22. A material usable for the electrostatic attracting film 22 is a dielectric material such as aluminum oxide, titanium oxide containing aluminum oxide or the like. As the electric source 23, a direct current source of several hundred volts can be used.

14

A pulse bias electric power source 17 for supplying a pulse bias having an amplitude of 20 V to 1000 V is connected to the lower electrodes 15A, 15B through blocking capacitors 19A, 19B for cutting Direct current components, respectively.

Although the electrostatic chuck of a two-pole type has been described above, an electrostatic chuck of another type such as a single-pole type or an e-pole type ( $n \geq 3$ ) may be applicable.

When etching is performed, the sample 40 of an object to be processed is mounted on the lower electrode 15 in the processing chamber 10 and attracted by the electrostatic chuck 20. On the other hand, a gas required for etching the sample 40 is supplied to the processing chamber 10 from the gas supplying unit 36 through the gas introducing chamber 34. The outer chamber 11 is vacuum-pumped by the vacuum pump 18 to be evacuated and depressurized so that pressure of the processing chamber becomes a processing pressure of the sample, for example, a pressure of 0.4 Pa to 4.0 Pa. Then, a high frequency electric power of 30 MHz to 300 MHz, preferably 50 MHz to 200 MHz, is output from the high frequency electric power source 16 to form the processing gas in the processing chamber 10 into a plasma.

By the high frequency electric power of 30 MHz to 300 MHz and the portion of static magnetic field of 10 gauss to 110 gauss formed by the magnetic field forming means 200, cyclotron resonance of electrons is generated between the upper electrode 12 and the lower electrode 15 to form a plasma having a low pressure, 0.4 to 4.0 Pa in this case, and a high density.

On the other hand, a pulse bias voltage of 20 V to 1000 V having a period of 0.1  $\mu$ s to 10  $\mu$ s, preferably 0.2  $\mu$ s to 5  $\mu$ s, and a duty in a positive pulse portion of 0.05 to 0.4 is applied to the lower electrode 15 from the pulse bias electric power source 17 to etch the sample while the electrons and the ions in the plasma are being controlled.

The etching gas is formed in a desired distribution by the gas diffusion plate 32 and then introduced into the processing chamber 10 through the holes 38 bored in the upper electrode 12 and the upper electrode cover 30.

Materials which can be used for the upper electrode cover 30, include carbon, silicon or a material containing carbon or silicon which removes the components of fluorine and/or oxygen to improve the selectivity to the resist and/or silicon to the base material.

In order to improve the micro workability of a large diameter sample, it is preferable that a plasma generating high frequency electric power source 16 having a high frequency is used to attempt to stabilize discharge in a low pressure region. In the present invention, the plasma generating high frequency electric power source 16 is connected to the upper electrode 12 in order to obtain a plasma which is a low pressure of 0.4 Pa to 4.0 Pa and a plasma density of  $5 \times 10^{10}$  to  $5 \times 10^{11}$   $\text{cm}^{-3}$ , and dissociation of the processing gas is not excessively progressed and has a uniform and large diameter. On the other hand, an ion energy controlling bias electric source 17 is connected to the lower electrode 15 mounting the sample, and the distance between the electrodes is set between 30 mm to 100 mm.

Further, using a VHF voltage of 30 MHz to 300 MHz, preferably 50 MHz to 200 MHz, for the plasma generating high frequency electric power source 16, and by the interaction with the portion of the static magnetic field or the low frequency (lower than 1 kHz) magnetic field having an intensity of 10 gauss to 110 gauss, preferably 17 gauss to 72 gauss, cyclotron resonance of electrons is formed between the upper electrode 12 and the lower electrode 15.

FIG. 2 shows an example of the change in plasma density when the frequency of a high frequency electric power source for generating a plasma is changed under a condition where a magnetic field for producing cyclotron resonance of electrons is applied. The gas used is argon with 2 to 10% of  $C_4F_8$  added thereto, and the pressure of the processing chamber is 1 Pa. The plasma density in the figure is shown as a normalized value by letting the density in a case of a microwave ECR with  $f=2450$  MHz be 1 (one). The dashed line in the figure shows a result obtained in a case without a magnetic field.

The plasma density is lower by one order to two orders compared to that in the microwave ECR when the frequency is in the range of  $50 \text{ MHz} \leq f \leq 200 \text{ MHz}$ . Further, dissociation of the gas is also decreased and generation of unnecessary fluorine atoms, molecules and ions is decreased by one order or more. By using the frequency in the VHF band and cyclotron resonance, a plasma having appropriately high density, namely, a plasma density above  $5 \times 10^{10} \text{ cm}^{-3}$  in absolute value is obtained, and a high rate processing is also possible under a low pressure of 0.4 Pa to 4.0 Pa. Furthermore, since dissociation of the gas is not excessively progressed, the selectivity of an insulator film such as  $\text{SiO}_2$  to the base material such as Si or SiN is not appreciably degraded.

When the frequency is within the range of  $50 \text{ MHz} \leq f \leq 200 \text{ MHz}$ , the dissociation of the processing gas is slightly progressed compared to that in a conventional apparatus of parallel flat plate electrode type using a frequency of 13.56 MHz, and the disadvantage of a small increase in the amount of fluorine atoms and/or molecules and/or ions can be eliminated by providing a material containing silicon or carbon to the surface of the electrodes and wall surface of the chamber, and further by applying a bias voltage to the electrodes and the wall surface of the chamber or by exhausting fluorine through coupling the fluorine with hydrogen using a gas containing hydrogen atoms.

When the frequency of the high frequency electric power source is above 200 MHz, particularly, above 300 MHz, the plasma density becomes high. However, it is not preferable since the dissociation of the processing gas becomes large and fluorine atoms and/or molecules and ions are extremely increased, and consequently the selectivity to the base material is largely degraded.

FIG. 3 shows an energy gains  $k$  of electrons obtained from a high frequency electric field under conditions with and without cyclotron resonance. Letting an energy obtained by an electron during one cycle of a high frequency source under a condition without the magnetic field be  $e_0$ , and an energy obtained by an electron during one cycle of a high frequency source under a condition applied with a cyclotron resonance magnetic field  $B_c = 2\pi f \cdot (m/e)$  be  $e_1$ ,  $e_0$  and  $e_1$  are expressed as the following equations:

$$e_0 = (e^2 E^2 / 2m) \{ v / (v^2 + \nu^2) \}$$

$$e_1 = (e^2 E^2 / 4m) \{ 1 / (v^2 + (\nu - \omega)^2) + 1 / (v^2 + (\nu + \omega)^2) \} \quad (\text{Equation 1})$$

where  $E$  is the intensity of the electric field.

Letting the ratio  $(=e_1/e_0)$  be  $k$ ,  $k$  is expressed by the following equation, where  $m$  is the mass of an electron,  $e$  is the charge of an electron and  $f$  is charged frequency:

$$k = (1/2) \{ (\nu^2 + \nu^2) \{ 1 / (v^2 + (\nu - \omega)^2) + 1 / (v^2 + (\nu + \omega)^2) \} \}$$

where  $\nu$  is collision frequency,  $\omega$  is exciting angular frequency, and  $\omega c$  is cyclotron angular frequency.

In general, the value  $k$  becomes larger as the gas pressure is lower and the frequency is higher. FIG. 3 is a result obtained using argon gas in which  $k \geq 150$  when  $f \geq 50 \text{ MHz}$  under a condition of pressure  $P=1$  Pa, and dissociation of the processing gas is progressed even under a low pressure compared to in a case without the magnetic field. The cyclotron resonance effect is rapidly decreased under a condition of pressure  $P=1$  Pa when the frequency is below nearly 20 MHz. It can be understood from the characteristic shown in FIG. 2 that when the frequency is lower than 30 MHz, there is little difference in the result from that in a case without the magnetic field, and the cyclotron resonance effect is small.

Although the cyclotron resonance effect can be increased by decreasing the gas pressure, electron temperature of the plasma is increased and there occurs an opposite effect in that the dissociation of the gas is excessively progressed when the gas pressure is lower than 1 Pa. In order to suppress the excessive dissociation of gas and to increase the plasma density above  $5 \times 10^{10} \text{ cm}^{-3}$ , the gas pressure is set to at a value in the range of 0.4 Pa to 4 Pa, preferably, 1 Pa to 4 Pa.

In order to attain an effective cyclotron resonance effect, it is necessary to set the value  $k$  to several tens or larger. It can be understood from FIG. 2 and FIG. 3 that in order to effectively use the cyclotron resonance effect without excessively progressing dissociation of the gas, it is required to set the gas pressure to a value of 0.4 Pa to 4 Pa and to use a VHF of 30 MHz to 300 MHz, preferably, 50 MHz to 200 MHz for plasma generating high frequency electric power.

FIG. 4 shows the relationship between intensity of a magnetic field and an ion acceleration voltage  $V_{DC}$  induced in a sample, deviation  $\Delta V$  of an induced voltage in the sample when an upper electrode of a magnetron discharge electrode is grounded and a lower electrode is applied with a magnetic field  $B$  and a high frequency electric power. As the intensity of magnetic field is increased, the ion acceleration voltage  $V_{DC}$  becomes small by Lorentz force action on electrons and consequently the plasma density is increased. However, since the intensity of magnetic field  $B$  is as large as 200 gauss in the conventional magnetron discharge type, there is a disadvantage in that uniformity of plasma density in the surface is degraded and the deviation  $\Delta V$  of the induced voltage becomes large to increase damage of the sample.

It can be understood from FIG. 4 that in order to decrease the deviation  $\Delta V$  to  $1/5$  to  $1/10$  of that in the conventional magnetron discharge type having a magnetic field intensity of 200 gauss, in order to eliminate sample damage the intensity of the magnetic field  $B$  is set to a value below 30 gauss near the sample surface, preferably, set to a value smaller than 15 gauss.

A cyclotron resonance region is formed between the upper electrode 12 and the lower electrode 15 and slightly on the side of the upper electrode from the middle position of both electrodes. The abscissa in FIG. 5 indicates distance from the sample surface (the lower electrode 15) to the upper electrode 12, and the ordinate indicates magnetic field. FIG. 5 shows an example obtained under a condition of an applied frequency  $f_1$  of 100 MHz,  $B_c$  of 37.5 G and a distance between the electrodes of 50 mm, in which an ECR region is formed in a position about 30 mm from the sample surface.

As described above, in the present invention, a portion where the component of magnetic field parallel to the lower electrode 15 (the sample mounting surface) becomes maximum is set on the upper electrode surface or on the side of

# US 6,197,151 B1

17

the upper electrode from the middle position between the two electrodes. By doing so, the intensity of the magnetic field parallel to the sample on the lower electrode surface is set to a value smaller than 30 gauss, preferably, smaller than 15 gauss to make the Lorentz force (EXB) acting on electrons near the lower electrode surface a small value, and consequently it is possible to eliminate the non-uniformity in the plane of plasma density due to the electron drift effect caused by Lorentz force on the lower electrode surface.

According to the magnetic field forming means 200 in the embodiment of FIG. 1, the ECR region is formed nearly in the same level from the lower electrode 15 (the sample mounting surface) except for the central portion of the sample, as shown in FIG. 6. Therefore, a sample having a large diameter can be plasma-processed uniformly. However, the ECR region in the central portion of the sample is formed in a position of higher level from the sample mounting surface. Since the distance between the ECR region and the sample table is larger than 30 mm, ions and radicals are diffused and averaged in the gap. Therefore, there is no problem in a general plasma processing operation. However, in order to perform plasma-processing all over the sample uniformly, it is preferable that the ECR region is formed in a position of the same level from the sample surface all over the surface of the sample, or the ECR region is formed in a position slightly closer to the periphery of the sample table compared to the level of the ECR region in the central portion. The method of forming such a plasma will be described later.

As described above, in the embodiment of the present invention shown in FIG. 1, since a VHF voltage of 30 MHz to 300 MHz forming the plasma generating high frequency electric power source 16 is used and dissociation of the processing gas is progressed by electron cyclotron resonance, it is possible to obtain a stable plasma even when gas pressure inside the processing chamber is as low as 0.4 Pa to 4 Pa. Further, since ion collision in the sheath is reduced, moving directions of ions during processing the sample 40 are well aligned to improve the verticality in the fine pattern processing.

In regard to the surrounding of the processing chamber 10, since the plasma is confined in the vicinity of the sample 40 by the discharge confining ring 37, the plasma density is increased and attaching of unnecessary deposits to portions outside the discharge confining ring 37 is minimized.

A material used for the discharge confining ring 37 is a semiconductor material or a conductor material such as carbon, silicon or SiC. When the discharge confining ring 37 is connected to a high frequency electric power source to cause sputtering by ions, it is possible to decrease attaching of deposits to the ring 37 and also to remove fluorine.

Since fluorine can be removed by providing a susceptible cover 39 made of carbon, silicon or a material containing carbon or silicon on the insulator member 13 near the sample when an insulator film such as SiO<sub>2</sub> is plasma-processed using a gas containing fluorine, the selectivity can be improved. In this case, when the thickness of the insulator member 13 in a portion under the susceptible cover 39 is thinned to 0.5 mm to 5 mm, the effect described above can be promoted by the sputtering effect by ions.

Further, an electrostatic attracting circuit is formed through the lower electrode 15 (15A, 15B) and the sample 40 interposing the electrostatic attracting film 22 of dielectric material. In this state, the sample 40 is held and maintained onto the lower electrode 15 by an electrostatic force. Along the back side surface of the sample 40 held by the electrostatic attracting force, a heat transfer gas such as

18

helium, nitrogen, argon or the like is supplied. The heat transfer gas is filled between the back side surface of the sample 40 and the lower electrode 15, and the heat transfer gas is set to a pressure of several hundreds pascals to several thousands pascals. It is considered that the electrostatic attracting force is nearly zero between the indented portions existing in gaps and acts only in the projecting portions of the lower electrode 15. However, as described later, since it is possible to set an attracting force large enough to withstanding the pressure of the heat transfer gas by properly setting a voltage of the direct current electric power source 23, the sample 40 cannot be moved or blown off by the heat transfer gas.

The electrostatic attracting film 22 acts to decrease the bias function of pulse bias to ions in the plasma. The function exists in a conventional method of biasing using a sinusoidal electric power source, but the problem does not clearly appear. However, the problem becomes clear in the pulse bias method since the characteristic of the pulse bias method of narrow ion energy width is lost.

The present invention is characterized by a voltage suppressing means that is provided in order to suppress the increase of the voltage difference generated between the ends of the electrostatic attracting film 22 accompanied by application of the pulse bias to increase the pulse bias effect.

As an example of the voltage suppressing means, it is preferable that the voltage change ( $V_{CM}$ ) in one cycle of the bias voltage generated between the ends of the electrostatic attracting film accompanied by application of the pulse bias is lower than one-half of the voltage ( $V_p$ ) of the pulse bias. In detail, there is a method for increasing the electrostatic capacity of the dielectric member by thinning a thickness of the electrostatic attracting film made of a dielectric material provided on the surface of the lower electrode, or by employing a material having a large specific dielectric coefficient.

Further, as another example of the voltage suppressing means, there is a method of suppressing the increase of the voltage  $V_{CM}$  by shortening the period of the pulse bias voltage. Furthermore, it is also considered that the electrostatic attracting circuit and the pulse bias voltage applying circuit are separately arranged in different positions, for example, another different electrode opposite to the electrode mounting and holding the sample, or a third electrode provided separately.

Description will be made in detail below on the relationship between the voltage change ( $V_{CM}$ ) in one cycle of the bias voltage generated between the ends of the electrostatic attracting film and the pulse bias voltage which should be brought by the voltage suppressing means in accordance with the present invention, referring to FIG. 7 to FIG. 13.

FIGS. 7(A) and 7(B) show an example of a desirable output waveform used in the pulse bias power source 17 in accordance with the present invention. In the figure, pulse amplitude is  $V_p$ , pulse period is  $T_0$ , and positive direction pulse width is  $T_1$ .

When the wave-form of FIG. 7(A) is applied to a sample though a blocking capacitor and an electrostatic attracting dielectric layer (hereinafter referred to as electrostatic attracting film), the voltage wave-form on the surface of the sample under a steady-state condition where a plasma is generated by another power source becomes as shown in FIG. 7 (B). Referring to the labelling of FIG. 7(B),  $V_{DC}$  is direct current component voltage of the wave-form  $V_f$  is floating potential of the plasma, and  $V_{CM}$  is maximum voltage during one cycle of the voltage produced between both ends of the electrostatic attracting film.

The portion (1) which is positive voltage to  $V_f$  in FIG. 7(B) is a portion where only electron current is mainly dragged, the portion which is negative voltage to  $V_f$  is a portion where ion current is dragged, and the portion  $V_f$  is a portion where electrons and ions are balanced. The voltage  $V_f$  is generally several volts to several tens of volts.

In the description according to FIG. 7(A) and thereafter, it is assumed that the capacitance of the blocking capacitor and the capacitance of the insulator member near the sample surface are sufficiently larger than the capacitance of the electrostatic attracting film (hereinafter referred to as electrostatic attracting capacitance).

The value  $V_{CM}$  is expressed by the following equation:

$$V_{CM} = (q/c) = \{i_i \times (T_0 - T_1)\} / \{(\epsilon_r \epsilon_0 / d) \times K\} \quad (\text{Equation 2})$$

In this equation,  $q$  is ion current density (averaged value) entering into the sample during the period of  $(T_0 - T_1)$ ,  $i_i$  is ion current density,  $d$  is film thickness of the electrostatic attracting film,  $K$  is electrode cover ratio of the electrostatic attracting film ( $\leq 1$ ),  $\epsilon_r$  is the specific dielectric constant of the electrostatic attracting film, and  $\epsilon_0$  is dielectric constant of vacuum (constant value).

FIGS. 8(A) to 8(E) and FIG. 9 show electric potential wave-forms on the sample surface and probability distribution of ion energy when  $T_0$  is varied while a pulse duty ratio ( $T_1/T_0$ ) is being kept constant. Therein,  $T_{01}:T_{02}:T_{03}:T_{04}:T_{05}=16:8:4:2:1$ .

As shown in FIG. 8(A), when the pulse period  $T_0$  is too large, the electric potential on the sample surface is largely deformed from a rectangular wave-form and becomes a triangular wave-form. The distribution of ion energy becomes constant from a low ion energy region to a high ion energy region, as shown in FIG. 9, which is not preferable.

As shown in FIGS. 8(B) to (E), as the pulse period  $T_0$  is decreased to small, the value ( $V_{CM}/V_p$ ) becomes smaller than 1 (one), and the ion energy distribution is also narrowed.

In FIGS. 8(A) to 8(E) and FIG. 9, the relationship  $T_0=T_{01}, T_{02}, T_{03}, T_{04}, T_{05}$  corresponds to ( $V_{CM}/V_p$ )=1, 0.63, 0.31, 0.16, 0.08.

Next, FIG. 10 shows the relationship between pulse OFF period ( $T_1 - T_0$ ) and maximum voltage  $V_{CM}$  during one cycle of a voltage induced between both ends of the electrostatic attracting film.

The solid bold line (line for reference condition) in FIG. 10 shows change of the value  $V_{CM}$  in a plasma having a medium density of ion current density  $i_i=5 \text{ mA/cm}^2$  when about 50% of the area of the electrode ( $K=0.5$ ) is flattened to touch to the back side of the sample 40, and is covered with aluminum oxide containing titanium oxide ( $\epsilon_r=10$ ) with a thickness of 0.3 mm.

It can be understood from FIG. 10 that as the pulse OFF period ( $T_1 - T_0$ ) is increased, the voltage  $V_{CM}$  induced between both ends of the electrostatic attracting film is increased proportional to the period and becomes higher than the pulse voltage  $V_p$  generally used.

For example, in a plasma etching apparatus, the pulse voltage  $V_p$  is generally limited as follows in connection to occurrence of damage, selectivity to base material and/or a mask, a shape and so on:

For gate etching:  $20 \text{ volts} \leq V_p < 100 \text{ volts}$

For metal etching:  $50 \text{ volts} \leq V_p < 200 \text{ volts}$

For oxide film etching:  $250 \text{ volts} \leq V_p < 1000 \text{ volts}$

When it is tried to satisfy the condition ( $V_{CM}/V_p$ ) $\leq 0.5$ , to be described later, in the reference condition, the limit in the pulse OFF period ( $T_1 - T_0$ ) becomes as follows:

For gate etching:  $(T_1 - T_0) \leq 0.15 \mu\text{s}$

For metal etching:  $(T_1 - T_0) \leq 0.35 \mu\text{s}$

For oxide film etching:  $(T_1 - T_0) \leq 1.2 \mu\text{s}$

When  $T_0$  approaches to  $0.1 \mu\text{s}$ , unnecessary plasma is generated and the bias electric source is not effectively used for ion acceleration since the impedance of the ion sheath approaches to or becomes lower than the impedance of the plasma. Thereby, controllability of ion energy by the bias electric power source is degraded. Therefore, it is desired that the period  $T_0$  is larger than  $0.1 \mu\text{s}$ , preferably, larger than  $0.2 \mu\text{s}$ .

In a gate etching apparatus in which  $V_p$  can be suppressed to a low value, it is necessary to employ a material having a specific dielectric constant as high as 10 to 100 for the electrostatic attracting film, for example, a dielectric constant  $\epsilon_r$  of  $\text{Ta}_2\text{O}_5$  is 25, and to also decrease the film thickness, for example, to a thickness of  $10 \mu\text{m}$  to  $400 \mu\text{m}$ , preferably, to a thickness of  $10 \mu\text{m}$  to  $100 \mu\text{m}$ , without reducing the insulating withstanding voltage.

In FIG. 10, there are also shown the values of  $V_{CM}$  when electrostatic capacitance per unit area is increased by 2.5 times, 5 times and 10 times. Even if an electrostatic attracting film is improved, it is thought that the electrostatic capacitance  $c$  can be increased by several times in the present situation. Assuming  $V_{CM} \leq 300 \text{ volts}$ ,  $c \leq 10c_0$ , the following relation can be obtained:

$$0.1 \mu\text{s} \leq (T_0 - T_1) \leq 10 \mu\text{s}.$$

A portion effective for plasma processing by ion acceleration is the portion ( $T_0 - T_1$ ), and therefore it is preferable that the pulse duty ( $T_1/T_0$ ) is as small as possible.

FIG. 11 shows ( $V_{DC}/V_p$ ) which means an efficiency of plasma processing taking time average into consideration. It is preferable to make ( $T_1/T_0$ ) small and ( $V_{DC}/V_p$ ) large.

Assuming ( $V_{DC}/V_p$ ) $\geq 0.5$  as an efficiency of plasma processing and taking a condition to be described later ( $V_{DC}/V_p$ ) $\leq 0.5$ , the pulse duty becomes ( $T_1/T_0$ ) $\leq$  approximately 0.4.

The pulse duty ( $T_1/T_0$ ) is effective for ion energy control when it is small. However, when it is unnecessarily small, a pulse width  $T_1$  becomes as small as  $0.05 \mu\text{s}$  and consequently the pulse bias contains frequency components in the range of several tens of MHz. As a result, it becomes difficult to separate from the plasma generating high frequency component which is to be described later. As shown in FIG. 11, since decrease of ( $V_{DC}/V_p$ ) in the range of  $0 \leq (T_1/T_0) \leq 0.05$  is small, no problem occurs when ( $T_1/T_0$ ) is set to a value above 0.05.

As an example of gate etching, FIG. 12 shows an energy dependence of the silicon etching rate  $\text{ESi}$  and oxide film etching rate  $\text{ESiO}_2$  when chlorine gas of  $10 \text{ mTorr}$  is formed in a plasma. The silicon etching rate  $\text{ESi}$  becomes a constant value in a low ion energy region. In a region of ion energy above approximately  $10 \text{ V}$ ,  $\text{ESi}$  increases as the ion energy increases.

On the other hand, the etching rate  $\text{ESiO}_2$  for the oxide film of the base material is zero when the ion energy is smaller than nearly  $20 \text{ V}$ , and when the ion energy exceeds nearly  $20 \text{ V}$ , the etching rate  $\text{ESiO}_2$  increases as the ion energy is increased.

As a result, when the ion energy is below nearly  $20 \text{ V}$ , there is a region where the selectivity to the base material  $\text{ESi}/\text{ESiO}_2$  becomes  $\infty$  (infinity). When the ion energy is above nearly  $20 \text{ V}$ , the selectivity  $\text{ESi}/\text{ESiO}_2$  to the base material rapidly decreases as the ion energy is increased.

As an example of etching of an oxide film ( $\text{SiO}$ , BPSG, HISO, TEOS or the like) as a kind of insulator films, FIG.

13 shows ion energy distributions of the oxide film etching rate  $\text{ESiO}_2$  and silicon etching rates  $\text{ESi}$  when  $\text{C}_4\text{F}_8$  gas of 1.0 Pa is formed in a plasma.

The oxide film etching rate  $\text{ESiO}_2$  becomes negative and deposits are produced when the ion energy is low. The oxide film etching rate  $\text{ESiO}_2$  steeply increases at the ion energy of nearly 400 V, and after that gradually increases. On the other hand, the etching rate  $\text{ESi}$  for silicon to be used as the base material is switched from negative (etching) to positive (etching) at an ion energy higher than the ion energy where  $\text{ESiO}_2$  is switched from negative to positive, and then gradually increases.

As the result, the selectivity  $\text{ESi}/\text{ESiO}_2$  to the base material becomes  $\infty$  (infinity) at an ion energy where  $\text{ESiO}_2$  is switched from negative to positive, and in the ion energy above the switching point the selectivity  $\text{ESi}/\text{ESiO}_2$  steeply decreases as the ion energy increases.

When the results of FIG. 12 and FIG. 13 are applied to a practical process, ion energy is set to an appropriate value by adjusting the bias electric power source with taking the values of  $\text{ESi}$ ,  $\text{ESiO}_2$ ,  $\text{ESi}/\text{ESiO}_2$ , and the magnitude of the value  $\text{ESi}/\text{ESiO}_2$ .

A better characteristic can be obtained by switching the ion energy just before and just after etching, that is, etching until exposing a base film, with giving a priority to the etching rate just before the etching and giving a priority to the selectivity just after the etching.

The characteristic shown in FIG. 12 and FIG. 13 is a characteristic for a case where the ion energy distribution is limited in a narrow range. Since an etching rate for a case where the ion energy distribution spreads in a wide range is expressed by the time averaged value, it cannot be set at the optimum value and accordingly the selectivity is substantially degraded.

According to an experiment, when the value  $(V_{DC}/V_p)$  was smaller than about 0.3, a deviation of ion energy was smaller than nearly  $\pm 15\%$ , and a high selectivity higher than 30 was attained with the characteristic of FIG. 12 and FIG. 13. Further, as far as  $(V_{DC}/V_p) \leq 0.5$ , the selectivity was improved compared to a conventional sinusoidal wave bias method.

As described above, as the voltage suppressing means for suppressing the voltage change  $(V_{CM})$  in one cycle of the bias voltage generated between the ends of the electrostatic attracting film, it is preferable that the voltage change  $(V_{CM})$  is lower than one-half of the voltage  $(V_p)$  of the pulse bias. In detail, there is a method to decreasing a thickness of the electrostatic chuck film 22 made of a dielectric material provided on the surface of the lower electrode 15, or by employing a material having a large specific dielectric coefficient. Further, there is a method to suppress the voltage change between the ends of the electrostatic attracting film by shortening the period of the pulse bias voltage to 0.1  $\mu\text{s}$  to 10  $\mu\text{s}$ , preferably, 0.2  $\mu\text{s}$  to 5  $\mu\text{s}$  (corresponding to repeating frequency of 0.2 MHz to 5 MHz) so that the pulse duty  $(T_1/T_0)$  is set as  $0.05 \leq (T_1/T_2) \leq 0.4$ .

Furthermore, it is possible to make the voltage change  $(V_{CM})$  in one cycle of the bias voltage generated between the ends of the electrostatic attracting film satisfy the above-described condition  $(V_{DC}/V_p) \leq 0.5$ .

An embodiment of using the vacuum processing chamber for etching of an insulator film ( $\text{SiO}$ , BPSG, TEOS, HISO or the like) will be described below.

A processing gas 36 used for the etching operation is composed of  $\text{C}_4\text{F}_8$  of 1 to 5%, Ar of 90 to 95% and  $\text{O}_2$  of 0 to 5%; or  $\text{C}_4\text{F}_8$  of 1 to 5%, Ar of 70 to 90%,  $\text{O}_2$  of 0 to 5% and CO of 10 to 20%. The plasma generating high frequency

electric power source 16 used has a higher frequency, for example 40 MHz, compared to a conventional one to stabilize discharge under a low pressure range of 1 to 3 Pa.

When dissociation of the processing gas progresses to exceed the necessary amount by using the high frequency of the plasma generating high frequency power source 16, the output of the high frequency power source 16 is ON-OFF controlled or level modulation controlled using a high frequency electric power modulating signal source 161. When the level is high, ions are generated more than generation of radicals, and when the level is low, radicals are generated more than generation of ions. An ON time (or the high level time for the level modulation) used is 5 to 50  $\mu\text{s}$ , and an OFF time (or the low level time for the level modulation) used is 10 to 200  $\mu\text{s}$ , while a period used is 20 to 250  $\mu\text{s}$ . By doing so, it is possible to avoid unnecessary dissociation and to attain a desired ion-radical ratio.

A modulating period of the plasma generating high frequency power source is generally longer than the period of the pulse bias. Therefore, the modulating period of the plasma generating high frequency power source is set to a value of an integer times the period of the pulse bias to optimize the phase between them. By doing so, the selectivity can be improved.

On the other hand, ion energy is controlled so that ions in the plasma are accelerated and vertically irradiated onto the sample by applying a pulse bias voltage. By using an electric power source having, for example, a pulse bias period T of 0.65  $\mu\text{s}$ , a pulse width T1 of 0.15  $\mu\text{s}$  and a pulse amplitude  $V_p$  of 800 V as the pulse bias power source 17, it is possible to perform plasma processing having a better characteristic in which the width of ion energy distribution is  $\pm 15\%$  and the selectivity to the base material is 20 to 50.

Another embodiment of a plasma etching apparatus of two-electrode type in accordance with the present invention will be described below, referring to FIG. 14. Although this embodiment has a similar construction as shown by FIG. 1, a different point of this embodiment from FIG. 1 is that the lower electrode 15 holding the sample has a single pole type electrostatic chuck 20. An electrostatic attracting dielectric layer 22 is provided on the upper surface of the lower electrode 15, and the positive side of the direct current source 23 is connected to the lower electrode 15 through a coil 24 for cutting the high frequency component. Further, the pulse bias electric power source 17 for supplying a positive pulse bias voltage of 20 V to 1000 V is also connected to the lower electrode through a blocking capacitor 19.

Discharge confining rings 37A, 37B are provided in the periphery of the processing chamber 10 to increase a plasma density and to minimize attaching of unnecessary deposits onto the outside portions of the discharge confining rings 37A, 37B. In the discharge confining rings 37A, 37B of FIG. 14, a diameter of the bank portion of the discharge confining ring 37A in the lower electrode side is formed smaller than a diameter of the bank portion of the discharge confining ring 37B in the upper electrode side so that distribution of reaction products around the sample is made uniform.

A material used for the discharge confining rings 37A, 37B, at least for the side facing the processing chamber side, is a semiconductor or a conductor such as carbon, silicon or SiC. Further, a bias electric power source 17A of 100 kHz to 13.56 MHz for the discharge confining ring is connected to the ring 37A in the lower electrode side through a capacitor 19A, and the ring 37B in the upper electrode side is constructed so that a part of the voltage of the high frequency electric power source 16 is applied to the ring 37B

in the upper electrode side. Thereby, attaching of deposits onto the rings 37A, 37B due to the sputtering effect of ions is decreased and the fluorine removing effect is provided.

The reference characters 13A, 13C of FIG. 14 are insulator members made of aluminum oxide or the like, and the reference character 13B is an insulator member having a conductor such as SiC, glassy carbon, Si or the like.

When the conductivity of the rings 37A, 37B is low, conductors made of a metal are embedded inside the rings 37A, 37B and distance between the surface of the ring and the embedded conductor is made small. Thereby, the high frequency electric power easily radiates from the surfaces of the rings 37A, 37B to decrease reduction of the sputter effect.

The upper electrode cover 30 is fixed to the upper electrode 12 generally only in the peripheral portion of the cover with bolts 250. A gas is supplied to the upper electrode cover 30 from the gas supply unit 36 through the gas introducing chamber 34, the gas diffusion plate 32 and the upper electrode 12. The holes provided in the upper electrode cover 30 have a very small diameter of 0.3 to 1 mm to reduce the likelihood of the occurrence of abnormal discharge in the hole. The gas pressure in the upper portion of the upper electrode cover 30 is a fraction of one atmospheric pressure to one-tenth of one atmospheric pressure. For example, a force of nearly 100 kg acts on the upper electrode cover 30 having a diameter of larger than 300 mm as a whole. Therefore, the upper electrode cover 30 is deformed in a convex shape to the upper electrode 12 and accordingly a gap is produced having several hundreds micro-meters near the central portion.

In that case, when the frequency of the high frequency electric power source 16 is increased up to approximately more than 30 MHz, resistance in the lateral direction of the upper electrode cover 30 cannot be neglected and particularly the plasma density near the central portion is decreased. In order to solve this problem, the upper electrode cover 30 is fixed to the upper electrode 12 in portions near the center side of the upper electrode cover, not the peripheral portion. In the embodiment of FIG. 14, the upper electrode cover is fixed to the upper electrode 12 in several portions near the central side of the upper electrode cover 30 using bolts 251 made of a semiconductor such as SiC or carbon or an insulator such as aluminum oxide to make distribution of the high frequency field applied from the upper electrode 12 side uniform.

The method of fixing the upper electrode cover 30 to the upper electrode 12 at least near the center of the cover is not limited to using the bolts 251 described above. For example, the upper electrode cover 30 may be fixed to the upper electrode 12 using a substance having adhesiveness all over the surface or at least near the center of the upper electrode cover.

In FIG. 14, the sample 40 to be processed is mounted on the lower electrode 15 and attracted by the electrostatic chuck 20, that is, by a Coulomb force produced between both ends of the electrostatic attracting film 22 by positive charge by the direct current electric power source 23 and negative charge supplied from the plasma.

The operation of this apparatus is the same as that of the two-electrode type plasma etching apparatus shown in FIG. 1. When etching is performed, the sample 40 of an object to be processed is mounted on the lower electrode 15 and attracted by an electrostatic force. While a processing gas is being supplied to the processing chamber 10 from the gas supplying unit 36, on the other hand, the processing chamber is evacuated and depressurized by the vacuum pump 18 so

that pressure of the processing chamber becomes a processing pressure of the sample, that is, a pressure of 0.5 Pa to 4.0 Pa. Then, the high frequency electric power source 16 is switched on to apply a high frequency electric power of 20 MHz to 500 MHz, preferably 30 MHz to 100 MHz, between the electrodes 12 and 15 to form the processing gas into a plasma.

On the other hand, a positive pulse bias voltage of 20 V to 1000 V having a period of 0.1  $\mu$ s to 10  $\mu$ s, preferably 0.2  $\mu$ s to 5  $\mu$ s, and a duty in a positive pulse portion of 0.05 to 0.4 is applied to the lower electrode 15 from the pulse bias electric power source 17 to etch the sample while the electrons and the ions in the plasma are being controlled.

By applying the pulse bias voltage in such a manner, ions and/or-electrons in the plasma are accelerated and vertically irradiated onto the sample to perform highly precise shape control or highly precise selectivity control. The characteristics required for the pulse bias power source 17 and the electrostatic attracting film 22 are the same as in the embodiment of FIG. 1, and accordingly detailed description will be omitted here.

A further embodiment according to the present invention will be described below, referring to FIG. 15 to FIG. 17.

Although this embodiment is similar to the plasma etching apparatus of the two-electrode type construction shown in FIG. 1, a different point of this embodiment from FIG. 1 is in construction of the magnetic field forming means 200. The core 201 of the magnetic field forming means 200 is eccentrically arranged and driven by a motor 204 so as to be rotated at a speed of several rotations per minute to several tens of rotations per minute around an axis corresponding to the center of the sample 40. The core 201 is grounded.

In order to perform plasma-processing all over the surface of the sample highly accurately, cyclotron resonance effect of electrons is larger in the peripheral portion or the portion outside of the peripheral portion than in the center so that generation of plasma becomes large in the peripheral portion or the portion outside of the peripheral portion of the sample than in the center of the sample. However, in the embodiment of FIG. 1, there is no ECR region in the central portion of the sample and the plasma density near the center of the sample sometimes becomes too low, as shown in FIG. 6.

In the embodiment of FIG. 15, the magnetic field distribution is varied by rotation of the eccentric core 201 of the magnetic field forming means 200, and accordingly in the central portion of the sample the ECR region is formed in a low position from the sample surface at time  $t=0$  and  $t=T_0$ , and formed in a high position from the sample surface at time  $t=(\frac{1}{2})T_0$ . Since the core 201 is rotated at a speed of several rotations per minute to several tens of rotations per minute, the averaged value of the magnetic field intensity in the middle portion between the electrodes in the direction parallel to the sample surface becomes nearly the same value by the time averaging due to the rotation, as shown in FIG. 17. That is, the ECR region is formed in nearly the same level from the sample surface except for the peripheral portion of the sample.

As shown by dash-and-dot lines in the core 201 portion of FIG. 15, the thickness of the core composing the magnetic circuit in the side near the eccentric central core is formed thin and the thickness of the core composing the magnetic circuit in the side far from the eccentric central core is formed thick. By doing so, uniformity of the magnetic field intensity is further improved.

A still further embodiment in accordance with the present invention will be described below, referring to FIG. 18 and FIG. 19. Although this embodiment is similar to the plasma

etching apparatus of the two-electrode type construction shown in FIG. 15, a different point of this embodiment from FIG. 15 is in construction of the magnetic field forming means 200. The core 201 of the magnetic field forming means 200 has a concave surface edge 201A in a portion corresponding to the center of the processing chamber and also has another edge 201B in the side position of the processing chamber. By operation of the concave surface edge 201A, the magnetic flux B has a component in the inclined direction. As a result, distribution of the magnetic field is varied and the component of the magnetic field intensity in the direction parallel to the sample surface is formed to be more uniform compared to on the case of FIG. 1, as shown in FIG. 19.

A further embodiment in accordance with the present invention will be described below, referring to FIG. 20. Although this embodiment is similar to the plasma etching apparatus of the two-electrode type construction shown in FIG. 15, a different point of this embodiment from FIG. 15 is in construction of the magnetic field forming means 200. The core 201 of the magnetic field forming means 200 is of a fixed type, and forms a magnetic circuit together with a core 205 arranged in a position corresponding to the central portion of the processing chamber. The core 205 is rotated around an axis passing through the center of the edge 201A together with an insulator member 203. By such a construction, the same as the embodiment of FIG. 15, the averaged position of the ECR region near the central portion of the sample is formed in nearly the same level from the sample surface all over the surface of the sample.

A still further embodiment of a two-electrode type plasma etching apparatus in accordance with the present invention will be described below, referring to FIG. 21 and FIG. 22. In this embodiment, the magnetic field forming means 200 has two pairs of coils 210, 220 in the circumferential portion of the processing chamber, and a rotating magnetic field is formed by successively switching the direction of the magnetic field in each of the pairs of coils as shown by the arrows (1), (2), (3), (4). The position of the center O-O' of the coils 210, 220 is set at a level in the upper electrode 12 side from the middle level between the electrodes 12 and 15. Thereby, the apparatus is constructed so that the magnetic field intensity on the sample 40 becomes smaller than 30 gauss, preferably, smaller than 15 gauss.

The distribution of the magnetic field intensity for each portion on the sample surface can be adjusted by appropriately choosing the position and the diameter of the coils 210, 220 so as to increase plasma generation in the periphery or the outer side of the periphery of the sample.

A further embodiment of a two-electrode type plasma etching apparatus in accordance with the present invention will be described below, referring to FIG. 23 and FIG. 24. In this embodiment, the magnetic field forming means 200 has a pair of coils 210' arranged in an arc-shape in a horizontal plane along the circumference of the circular processing chamber. The polarity of the magnetic field is varied with a constant period as shown by the arrows (1), (2) in FIG. 23 by controlling current flowing in the pair of coils 210'.

Since the magnetic flux expands with respect to a vertical plane in the central portion of the processing chamber as shown by the dashed lines in FIG. 24, the intensity of the magnetic field in the central portion of the processing chamber is reduced. However, the pair of coils 210' are curved along the processing chamber, and the magnetic flux B is concentrated in the central portion of the processing chamber. Therefore, the intensity of the magnetic field in the central portion of the processing chamber can be increased

compared to the embodiment of FIG. 22. In other words, in the embodiment of FIG. 23, it is possible to suppress a decrease in the magnetic field in the central portion of the processing chamber compared to in the embodiment of FIG. 22, and, accordingly, the uniformity of the magnetic field on the sample mounting surface of the sample table can be improved.

Further, by varying the polarity of the magnetic field with a certain period, drift effect of  $E \times B$  can be reduced.

In this type, two pair of coils as in the embodiment of FIG. 22 may be employed as the magnetic field forming means 200.

Further, instead of the arc-shaped coil 210' the magnetic field forming means 200 may employ a convex coil 210' shown in FIG. 25 which is formed by combining a plurality of straight shaped coil sections arranged along the circumference of the circular processing chamber 10. In this case, the magnetic flux B concentrates in the central portion of the processing chamber and, accordingly, the same effect as in the embodiment of FIG. 23 can be obtained.

Furthermore, as shown in FIG. 26, the center axis of a pair of coils may be inclined with respect to a vertical plane so as to approach the sample surface in the central portion of the processing chamber. According to this embodiment, since the magnetic field intensity in the central portion of the processing chamber can be increased and the magnetic field intensity in the peripheral portion of the processing chamber can be decreased, the uniformity of the magnetic field on the sample mounting surface of the sample table can be improved. In order to make the magnetic field intensity uniform, it is preferable that the inclining angle  $\theta$  of the center axis of the coil is set from 5 degrees to 25 degrees.

Further, as shown in FIG. 27, a pair of coils 210B are arranged near a pair of coils 210A. By controlling currents flowing in the two pair of coils, the position of the ECR resonance as well as the gradient of the magnetic field near the position of the ECR resonance are varied to change the width of the ECR resonance region. By optimizing the width of the ECR resonance region for each process, it is possible to obtain an ion/radical ratio suitable for each process.

It is possible to further improve the uniformity of magnetic field intensity distribution and the controllability by properly combining the embodiments of FIG. 23 to FIG. 27 described above, if necessary.

A still further embodiment of a two-electrode type plasma etching apparatus in accordance with the present invention will be described below, referring to FIG. 28 and FIG. 29. In this embodiment, a part of the processing chamber is made of a conductor and grounded. On the other hand, the magnetic field forming means 200 has coils 230, 240 in the peripheral portion and the upper portion of the processing chamber 10. The direction of the magnetic flux B formed by the coil 230 and the direction of the magnetic flux B' formed by the coil 240 cancel each other in the central portion of the processing chamber 10, and superpose each other in the peripheral portion and the outer portion of the peripheral portion of the processing chamber 10, as shown by the arrows. As a result, the distribution of the magnetic field intensity at each position of the sample surface becomes as shown in FIG. 29.

In addition to this, in the portion of the mounting surface for the sample 40, the direction of the electric field and the direction of the magnetic field between the upper electrode 12 and the lower electrode 15 are the same. On the other hand, in the portion outside the mounting surface for the sample 40, the component of the magnetic field in the vertical direction intersecting with the component of electric

field in the lateral direction at a right angle is formed in the peripheral portion of the upper electrode 12 and the portion between the upper electrode 12 and the wall of the processing chamber.

Therefore, according to the embodiment of FIG. 38, the cyclotron resonance effect of electrons in the central portion of the sample can be decreased and generation of plasma in the peripheral portion and the outside portion of the peripheral portion of the sample can be increased.

A further embodiment in accordance with the present invention will be described below, referring to FIG. 30. In the two-electrode type plasma etching apparatus shown in FIG. 1, there are some cases where sufficient ion energy cannot be obtained with the high frequency electric power  $f_1$  applied from the high frequency electric power source 16 to the upper electrode 12. In such a case, this embodiment increases the ion energy to 100 V to 200 V by applying a high frequency voltage  $f_3$  having a frequency, for example, below 1 MHz from a low frequency electric power source 163 to the upper electrode 12 as a bias. Here, the reference characters 164, 165 indicate filters.

An embodiment of a two-electrode type plasma etching apparatus of non-magnetic field type in accordance with the present invention will be described below, referring to FIG. 31.

As described above, in order to improve micro workability of a sample, it is preferable that a plasma generating high frequency electric power source 16 has a higher frequency and discharge under a low gas pressure is stabilized. In the embodiment of the present invention, the pressure processing a sample in the processing chamber is set to 0.5 to 4.0 Pa. By setting the gas pressure in the processing chamber 10 to a low pressure below 40 mTorr, probability of ion collision in the sheath is decreased. Therefore, in processing a sample 40, directivity of ions is increased and accordingly it becomes possible to perform vertical fine pattern. However, in order to attain the same processing rate under a pressure below 5 mTorr, the exhausting system and the high frequency electric power source become large in size, and dissociation of the processing gas occurs excessively due to increase of electron temperature, as a result, the processing characteristic is likely to be degraded.

In general, between a frequency of a plasma generating electric power source for a pair of electrodes and a minimum gas pressure capable of stably discharging, there is relationship that the lowest gas pressure for stable discharge is decreased as the frequency of the electric power source is increased and the distance between the electrodes is increased. In order to avoid ill effects such as attaching of deposits onto surrounding walls and onto the discharge confining ring 37 and to effectively perform a function of removing fluorine or oxygen by the upper electrode cover 30, the susceptible cover 39 and the resist in the sample, it is preferable that the distance between the electrodes is set to a value shorter than 50 mm which corresponds to a distance smaller than 25 times of mean-free-path at the maximum gas pressure of 40 mTorr. On the other hand, in order to attain stable discharge, the distance between the electrode is required to be 2 to 4 times (4 mm to 8 mm) or larger of the mean-free-path at the maximum gas pressure (40 mTorr).

In the embodiment shown in FIG. 31, since a high frequency electric power of 20 MHz to 500 MHz, preferably 30 MHz to 200 MHz, is used as the plasma generating high frequency electric power source 16, it is possible to obtain a stable plasma and to improve micro workability even if the gas pressure in the processing chamber is set to a low pressure of 0.5 to 4.0 Pa. Further, by using such a high

frequency electric power, dissociation of gas plasma is improved and controllability of selectivity during processing of a sample is improved.

In the embodiments of the present invention described above, the occurrence of interference between the output of the pulse bias electric power source and the output of the plasma generating electric power source can be considered. Therefore, the countermeasure for this problem will be described below.

In an ideal rectangular pulse having a pulse width of  $T_1$ , a pulse period of  $T_0$  and rise/fall speeds of infinity, as shown in FIG. 33, 70% to 80% of the electric power is included in the frequency range of  $f \leq 3f_0$  ( $f_0 = (1/T_1)$ ). However, the wave-form actually applied has rise/fall speeds of finite values, convergence of electric power is further improved and 90% of electric power can be included in the frequency range of  $f \leq 3f_0$ .

In order to uniformly apply a pulse bias having a high frequency component of  $3f_0$  over the surface of a sample, it is preferable to provide opposing electrodes parallel to the sample surface and to ground a pulse bias having a frequency component within a range of  $f \leq 3f_0$  where  $3f_0$  is obtained from Equation 3 as follows:

$$3f_0 = 3 \cdot (10^6 / 0.2) = 15 \text{ MHz, when } T = 0.2 \mu\text{s} \quad 3f_0 = 30 \text{ MHz, when } T = 0.1 \mu\text{s} \quad (\text{Equation 3})$$

In the embodiment shown in FIG. 31, a countermeasure is provided for interference between the output of the pulse bias electric power source and the output of the plasma generating electric power source. That is, in the plasma etching apparatus, the plasma generating high frequency electric power source 16 is connected to the upper electrode 12 opposite to the sample 40. In order to set the upper electrode 12 to the ground level of the pulse bias, the frequency  $f_1$  of the plasma generating electric power source 16 is set to a value larger than  $3f_0$  described above and the upper electrode 12 and the ground level are connected with a band eliminator 141 of which the impedance is large around  $f = f_1$  and small for the other frequencies.

On the other hand, the sample table 15 and the ground level are connected with a band pass filter 142 of which the impedance is small around  $f = f_1$  and large for the other frequencies. By constructing in such a way, the interference between the output of the pulse bias electric power source 17 and the output of the plasma generating electric power source 16 can be suppressed to a level which creates no problem and a better bias can be applied to the sample 40.

FIG. 34 shows an embodiment of a plasma etching apparatus of the induction coupling discharge type and the non-magnetic field type among the external energy supplying discharge type to which the present invention is applied. The reference character 52 indicates a flat coil, and the reference character 54 indicates a high frequency electric power source for applying a high frequency voltage of 10 MHz to 250 MHz to the flat coil. The plasma etching apparatus of the induction coupling discharge type can generate a stable plasma with a lower frequency and under a lower gas pressure compared to the type shown in FIG. 10. On the contrary, dissociation of gas is apt to be progressed. Therefore, unnecessary dissociation is prevented by modulating the output of the high frequency electric power source 1 using the high frequency electric power source modulating signal source 161, as shown in FIG. 1. The processing chamber 10 of a vacuum vessel comprises a sample table 15 which mounts the sample 40 on the electrostatic attracting film 22.

When etching is performed, the sample 40 of an object to be processed is mounted on the lower electrode 15 and

attracted by an electrostatic force. While a processing gas is being supplied to the processing chamber 10 from the gas supplying unit, not shown, on the other hand, the processing chamber is evacuated and depressurized by the vacuum pump so that pressure of the processing chamber becomes a processing pressure of the sample, that is, a pressure of 0.5 Pa to 4.0 Pa. Then, a high frequency electric power of 13.56 MHz is applied from the high frequency electric power source 54 to the flat coil 52 to form a plasma in the processing chamber 10. The sample 40 is etched using the plasma. On the other hand, during etching, a pulse bias voltage having a period of 0.1  $\mu$ s to 10  $\mu$ s, preferably 0.2  $\mu$ s to 5  $\mu$ s is applied to the lower electrode 15. The amplitude of the pulse bias voltage used is in a different range depending on the kind of the film, as described in the embodiment of FIG. 1. By applying the pulse bias voltage in such a manner, ions in the plasma are accelerated and vertically irradiated onto the sample to perform highly precise shape control or highly precise selectivity control. Accordingly, it is possible to perform accurate etching even if a resist mask pattern of the sample is of a submicron pattern.

In a plasma etching apparatus of the induction coupling discharge type and the non-magnetic field type, a Faraday shield plate 53 having a gap, which is grounded, and a thin shield plate protective insulator plate 54 having a thickness of 0.5 mm to 5 mm may be provided on the processing chamber 10 side of the induction high frequency magnetic field output portion. Since the capacitance component between the coil and the plasma is reduced by providing the Faraday shield plate 53, it is possible to reduce energy of ions impinging on a quartz plate under the coil 52 of FIG. 34 and the shield plate protective insulator plate 54 to reduce damage of the quartz plate and the insulator plate, and to prevent foreign from mixing into the plasma.

Further, since the Faraday shield plate 53 also serves as a grounded electrode for the pulse bias electric power source 17, it is possible to apply the pulse bias between the sample 40 and the Faraday shield plate 53 uniformly. In this case, no filter is required between the upper electrode and the sample table 15.

FIG. 36 is a vertical cross-sectional front view showing a part of a microwave processing apparatus to which the present invention is applied. A pulse bias electric power source 17 and a direct current source 13 are connected to a lower electrode 15 also serving as a sample table 15 mounting a sample 40 on an electrostatic attracting film 22. The reference character 41 indicates a magnetron of a microwave oscillating source, the reference character 42 indicates a microwave guide tube, and the reference character 43 indicates a quartz plate for vacuum-sealing a processing chamber 10, noting that these elements are used to supply the microwave to the processing chamber. The reference character 47 indicates a first solenoid coil for supplying a magnetic field, and the reference character 48 indicates a second solenoid coil for supplying a magnetic field. The reference character 49 indicates a process gas supplying system which supplies a process gas for performing processing such as etching, film-forming and so on into the processing chamber 10. The processing chamber 10 is evacuated by a vacuum pump, not shown. The characteristics required for the pulse bias electric power source 17 and the electrostatic chuck 20 are the same as in the embodiment of FIG. 1, and accordingly detailed description will be omitted here.

When etching is performed, the sample 40 of an object to be processed is mounted on the lower electrode 15 and

attracted by an electrostatic force. While a processing gas is being supplied to the processing chamber 10 from the gas supplying unit 49, on the other hand, the processing chamber is evacuated to a vacuum by the vacuum pump so that pressure of the processing chamber becomes a processing pressure of the sample, that is, a pressure of 0.5 Pa to 4.0 Pa. Then, the magnetron 41 and the first and the second solenoid coils 47, 48 are switched on, and a microwave generated in the magnetron 41 is guided to the processing chamber through the wave-guide tube 42 to produce a plasma. The sample 40 is etched using the plasma. On the other hand, during etching, a pulse bias voltage having a period of 0.1  $\mu$ s to 10  $\mu$ s, preferably 0.2  $\mu$ s to 5  $\mu$ s is applied to the lower electrode 15.

By applying the pulse bias voltage in such a manner, ions in the plasma are accelerated and vertically irradiated onto the sample to perform high precision shape control or high precision selectivity control. Thereby, it is possible to perform accurate etching processing even if a resist mask pattern of the sample is of a submicron pattern.

In the plasma etching apparatuses in accordance with the present invention depicted in FIG. 1 and the following figures, the direct current voltage of the electrostatic attracting circuit and the pulse voltage of the pulse bias electric power source circuit may be generated by superposing each other. Thereby, both circuits can be constructed in common. Further, the electrostatic attracting circuit and the pulse bias electric power source circuit may be separately provided so that the pulse bias does not adversely affect the electrostatic attraction.

Instead of the electrostatic attracting circuit in the embodiment of the plasma etching apparatus of FIG. 1, another attracting means such as a vacuum attracting means may be employed.

The above-mentioned plasma processing apparatuses having the electrostatic attracting circuit and the pulse bias voltage applying circuit in accordance with the present invention can be applied not only to an etching processing apparatus but also to a plasma processing apparatus such as a CVD apparatus by changing the etching gas to a CVD gas.

A description will be provided below regarding a further embodiment of a plasma etching apparatus capable of sub-micron plasma-processing by overcoming conventional disadvantages and by controlling quantity and quality of ions and radicals, referring to FIG. 37 depicting the further embodiment in accordance with the present invention.

A first plasma generating portion is provided in a place upstream of a vacuum processing chamber where a sample is placed noting that the first plasma generating portion is different from the vacuum processing chamber. Quasi-stable atoms generated in the first plasma generating portion are injected into the vacuum processing chamber, and then the quasi-stable atoms are formed into a second plasma in the vacuum processing chamber. In addition to the plasma etching apparatus shown in FIG. 1, an ion/radical forming gas supply unit 60 and a plasma generating chamber 62 for generating the quasi-stable atoms are provided. Further, a route for introducing a gas containing the quasi-stable atoms into the vacuum processing chamber and an introducing route connected to the ion/radical forming gas supply unit are provided in the upper electrode 12.

The characteristics of this embodiment are as follows.

(1) A gas supplied from the quasi-stable atom forming gas supply unit 36 is formed into a plasma by being applied with a high frequency electric power in the quasi-stable atom forming plasma generating chamber 62, and a required amount of quasi-stable atoms are generated in advance to be

31

introduced into the processing chamber 10. In order to efficiently generate the quasi-stable atoms, pressure of the quasi-stable atom forming plasma generating chamber 62 is set to a high pressure of several hundred mTorr to several tens of mTorr.

(2) On the other hand, a gas is introduced into the processing chamber from the ion/radical forming gas supply unit 60.

(3) A high frequency voltage having a comparatively small power is output from the plasma generating electric power source 16 to form a plasma in the processing chamber 10. Since ions are efficiently formed with electrons having a low energy lower than nearly 5 eV because of injection of the quasi-stable atoms, it is possible to obtain a plasma which is in a low electron temperature lower than 6 eV, preferably, lower than 4 eV and which has a very small amount of high energy electrons above 15 eV. Therefore, the radical forming gas is not excessively dissociated and accordingly a necessary quantity and a necessary quality of the radicals can be maintained. On the other hand, a quantity of the ions can be controlled by the amount of the quasi-stable atoms generated in the quasi-stable atom forming plasma generating chamber 62 and the amount of ion forming gas from the ion/radical forming gas supply unit 60.

Since the quantity and the quality of the ions and radicals can be controlled in such a manner, a better performance can be attained even in submicron plasma processing. The radical forming gas used is  $\text{CHF}_3$ ,  $\text{CH}_2\text{F}_2$ , or a fluorocarbon gas such as  $\text{C}_4\text{F}_4$  or  $\text{CF}_4$ , or adding a gas containing C and H such as  $\text{C}_2\text{H}_4$ ,  $\text{CH}_4$ ,  $\text{CH}_3\text{OH}$ , if necessary. The quasi-stable forming gas used is a gas composed of one kind or two kinds of rare gas as a base gas. The ion forming gas used is a gas having the following characteristic which efficiently forms ions.

The gas used as an ion forming gas is one having an ionization level which is lower than an energy level of the quasi-stable atoms, or a gas having an ionization level which is higher than an energy level of the quasi-stable atoms, noting, however, that the difference is as small as 5 eV or less.

It is also possible to use the quasi-stable atom forming gas or the radical forming gas described above instead of the ion forming gas, though the performance is likely to be degraded.

FIG. 38 shows a still further embodiment in accordance with the present invention in which a quantity and a quality of ions and radicals are controlled. This embodiment is the same as the embodiment of FIG. 37 in its basic idea. In FIG. 37, when the distance between the quasi-stable atom forming plasma chamber 62 and the vacuum processing chamber 10 is large, decay of the quasi-stable atoms in the passage becomes large. This embodiment is a countermeasure for such a case. The reference character 41 indicates a magnetron of a microwave oscillating source, the reference character 42 indicates a microwave guide tube, the reference character 43 indicates a quartz plate for vacuum-sealing a first plasma generating chamber 45 and allowing the microwave to pass through, and the reference character 44 is a quartz plate for diffusing gas. In the first plasma generating chamber 45, a plasma is generated by the microwave under a gas pressure of several hundred mTorr to several tens of mTorr to form quasi-stable atoms.

Since the distance between the place generating the quasi-stable atoms and the vacuum processing chamber in the apparatus of FIG. 38 is short compared with in the apparatus of FIG. 37, it is possible to inject the quasi-stable atoms with a high density and accordingly an amount of ions

32

in the vacuum processing chamber 10 can be increased. By maintaining the processing chamber 10 at a pressure of 5 to 50 mTorr and using the high frequency electric power source 16 having a frequency above 20 MHz, a high density and low electron temperature plasma having a density of order of  $10^{10}$  to  $10^{11}/\text{cm}^3$  and an electron temperature of 5 eV, preferably, 3 eV and dissociation of the ion forming gas is progressed while avoiding dissociation of  $\text{CF}_2$  which requires a dissociation energy of 8 eV. As a result, on the surface of the sample 40, the following reaction is mainly progressed with the assistance of incident ions accelerated at several hundred volts by the bias electric power source 17.

Since Si and SiN used as a base material are not etched by  $\text{CF}_2$ , it is possible to perform oxide film etching with a high selectivity.

Increases in the amount of fluorine due to partial dissociation of  $\text{CF}_2$  can be decreased by virtue of the upper electrode cover 30 being made of silicon, carbon or SiC.

As described above, by adjusting the radical forming gas and the ion forming gas the ratio of ions and radicals in the processing chamber 10 can be independently controlled, and consequently the reaction on the surface of the sample 40 can be easily controlled.

The plasma processing apparatus having the electrostatic attracting circuit and the pulse bias voltage applying circuit in accordance with the present invention can be applied not only to an etching processing apparatus but also to a plasma processing apparatus such as a CVD apparatus by changing the etching gas to a CVD gas.

FIG. 39 shows a further embodiment in accordance with the present invention in which a quantity and a quality of ions and radicals are independently controlled. In FIG. 39, the radical forming gas used is  $\text{CHF}_3$ ,  $\text{CH}_2\text{F}_2$ , or a fluorocarbon gas such as  $\text{C}_4\text{F}_4$  or  $\text{CF}_4$ , or adding a gas containing C and H such as  $\text{C}_2\text{H}_4$ ,  $\text{CH}_4$ ,  $\text{CH}_3\text{OH}$ , if necessary. The radical forming gas is introduced into the radical forming plasma generating chamber 62 through a valve 70 shown by an arrow A in FIG. 39.

In the radical forming plasma generating chamber 62, a plasma is generated by applying an output having a frequency of several MHz to several tens of MHz of an RF power source 63 to the coil 65 under a pressure of several hundred mTorr to several tens mTorr to produce mainly  $\text{CF}_2$  radicals. The amounts of  $\text{CF}_3$  and F produced at the same time are reduced by an H component.

Since it is difficult to largely reduce the amounts of CF and O components in the radical forming plasma generating chamber 62, an unnecessary component removing chamber 65 is provided downstream of the radical forming plasma generating chamber. In the unnecessary component removing chamber, an inner wall made of a material containing carbon or silicon such as carbon, Si, SiC or the like is provided to reduce the unnecessary components or to convert the unnecessary components into other gasses of less ill effect. A valve 71 is connected to an exit of the unnecessary component removing chamber 65 to supply a gas which is mainly composed of  $\text{CF}_2$ .

Since a large amount of sediment such as deposits is accumulated between the valve 70 and the valve 71, it is necessary to perform cleaning or exchanging that portion in a comparatively short period. Therefore, in order to easily perform opening-to-atmosphere and exchanging work and to shorten vacuum build-up time at restarting, the portion between the valve 70 and the valve 71 is connected to an evacuation system 74 through a valve 72. The evacuation

system 74 may also serve as an evacuation system for the processing chamber 10.

The ion forming gas of a rare gas such as argon gas, xenon gas or the like indicated by B in the figure is supplied to the processing chamber through a valve 73. The passage is connected to the exit of the valve 71.

By maintaining the processing chamber 10 at a pressure of 5 to 50 mTorr and using the high frequency electric power source 16 having a modulated frequency above 20 MHz, a high density and low electron temperature plasma is provided having a density on the order of  $10^{10}$  to  $10^{11}/\text{cm}^3$  and an electron temperature of 5 eV, preferably, 3 eV, and dissociation of the ion forming gas is progressed while avoiding dissociation of  $\text{CF}_2$  which requires a dissociation energy of 8 eV. As a result, on the surface of the sample 40, the following reaction is mainly progressed with assistance of incident ions accelerated at several hundred volts by the bias electric power source 17.

Since Si and SiN used as a base material are not etched by  $\text{CF}_2$ , it is possible to perform oxide film etching with a high selectivity.

Increases in the amount of fluorine due to partial dissociation of  $\text{CF}_2$  can be decreased by virtue of the upper electrode cover 30 being made of silicon, carbon or SiC.

As described above, by adjusting the radical forming gas A and the ion forming gas B, the ratio of ions and radicals in the processing chamber 10 can be independently controlled, and consequently the reaction on the surface of the sample 40 can be easily controlled. Further, since unnecessary deposits are removed by the unnecessary component removing chamber 65 so as to enter the processing chamber 10 to as small a degree as possible, the amount of deposits in the processing chamber 10 is substantially reduced and accordingly frequency of cleaning the processing chamber 10 by opening to the atmosphere is also substantially reduced.

FIG. 40 shows a further embodiment in accordance with the present invention in which a quantity and a quality of ions and radicals are independently controlled. Hexafluoropropylene oxide gas ( $\text{CF}_3\text{CFOCF}_2$ , hereinafter referred to as HFPO) is passed through a heating pipe portion 66 via a valve 70 from the portion indicated by A in the figure, and through an unnecessary component removing chamber 65 and a valve 71, and then mixed with an ion forming gas B to transfer toward the processing chamber 10. In the heating pipe portion 66, the HFPO is heated at a temperature of  $800^\circ\text{C}$ . to  $1000^\circ\text{C}$ . to form  $\text{CF}_2$  by thermal decomposition expressed by the following chemical formula:

Although  $\text{CF}_3\text{CFO}$  is comparatively stable and hardly decomposed, part of the  $\text{CF}_3\text{CFO}$  is decomposed to produce O and F. Therefore, the unnecessary component removing chamber 65 is provided downstream of the heating pipe portion 66 to remove the unnecessary components or convert to substances which will have ill effects. Although a part of the  $\text{CF}_3\text{CFOCF}_2$  flows into the processing chamber 10, there is no problem since it is not dissociated by the low electron temperature plasma below 5 eV.

Use of the valve 72 and the evacuating system 74 and reaction in the processing chamber is the same as described for the case of FIG. 39.

The plasma processing apparatus having the electrostatic attracting circuit and the pulse bias voltage applying circuit

in accordance with the present invention can be applied not only to an etching processing apparatus but also to a plasma processing apparatus such as a CVD apparatus by changing the etching gas to a CVD gas.

According to the present invention, it is possible to provide a plasma processing apparatus and a plasma processing method capable of easily performing precise working of a fine pattern to a large sized sample having a diameter of 300 mm or larger, and also capable of improving a selectivity during micro processing. Further, it is possible to provide a plasma processing apparatus and a plasma processing method capable of performing processing, particularly, oxide film processing all over the surface of a large sized sample uniformly and rapidly.

According to the present invention, it is possible to provide a plasma processing apparatus and a plasma processing method capable of improving the selectivity of plasma processing of insulator films such as  $\text{SiO}_2$ , SiN, BPSG and the like.

Further, it is possible to provide a plasma processing apparatus and a plasma processing method capable of improving the selectivity of plasma processing by obtaining a narrow ion energy distribution having better controllability. Furthermore, in a case of using a sample table having an electrostatic attracting dielectric layer, it is possible to provide a plasma processing apparatus and a plasma processing method capable of improving the selectivity of plasma processing by obtaining a narrow ion energy distribution having better controllability.

Further, it is possible to provide a plasma processing apparatus and a plasma processing method capable of easily performing precise working of a fine pattern and improving the selectivity during fine pattern processing. Furthermore, it is possible to provide a plasma processing apparatus and a plasma processing method capable of improving the selectivity of plasma processing of insulator films such as  $\text{SiO}_2$ , SiN, BPSG and the like by controlling the quantity and the quality of ions and radicals independently.

What is claimed is:

1. A plasma processing apparatus comprising a vacuum processing chamber, a plasma generating means including a pair of electrodes, a sample table having a sample mounting surface for mounting a sample to be processed inside said vacuum processing chamber, and a evacuating means for evacuating said vacuum processing chamber, which further comprises:

a high frequency electric power source for applying a high frequency electric power of a VHF band from 30 MHz to 300 MHz between said pair of electrodes; and

a magnetic field forming means for forming any one of a static magnetic field and a low frequency magnetic field in a direction intersecting an electric field generated between said pair of electrodes and the vicinity by said high frequency electric power source;

wherein an electron cyclotron resonance region being formed between said pair of electrodes by said magnetic field and said electric field.

2. A plasma processing apparatus comprising a vacuum processing chamber, a plasma generating means including a pair of electrodes, a sample table for mounting a sample to be processed inside said vacuum processing chamber and also serving as one of said electrodes, and a evacuating means for evacuating said vacuum processing chamber, which further comprises:

a high frequency electric power source for applying an electric power of a VHF band from 50 MHz to 200 MHz between said pair of electrodes; and

35

- a magnetic field forming means for forming any one of a static magnetic field and a low frequency magnetic field not weaker than 17 gauss and not stronger than 72 gauss in a direction intersecting an electric field generated between said pair of electrodes and the vicinity by said high frequency electric power source; 5
- wherein said magnetic field forming means being set so that a portion where a component of said magnetic field in a direction along the surface of said sample table becomes maximum is brought to a position in the opposite side of said sample table from the middle of said pair of electrodes; 10
- an electron cyclotron resonance region being formed between said pair of electrodes by said magnetic field and said electric field. 15
3. A plasma processing apparatus according to any one of claim 1 and claim 2, wherein
- intensity of the magnetic field formed by said magnetic field forming means is set so that a component of the magnetic field parallel to the surface of said sample table is not stronger than 30 gauss on the surface of said sample table. 20
4. A plasma processing apparatus comprising a vacuum processing chamber, a plasma generating means including a pair of electrodes, and a sample table for mounting a sample to be processed inside said vacuum processing chamber and also serving as one of said electrodes, which further comprises: 25
- a evacuating means for evacuating said vacuum processing chamber to 0.4 Pa to 4 Pa;

36

- a high frequency electric power source for applying an electric power of a VHF band from 30 MHz to 300 MHz between said pair of electrodes; and
- a magnetic field forming means for forming any one of a static magnetic field and a low frequency magnetic field not weaker than 10 gauss and not stronger than 110 gauss in a direction intersecting an electric field between said pair of electrodes and in the vicinity;
- said electrodes being composed of a first electrode connected to said high frequency electric power source and a second electrode also serving as said sample table connected to a bias electric power source for controlling ion energy, a distance between said pair of electrodes being 30 to 100 mm;
- an electron cyclotron resonance region being formed at a position within a range from the surface of said first electrode to the side of said first electrode from the middle of said pair of electrodes by interaction of said magnetic field and an electric field produced by said high frequency electric power source.
5. A plasma processing apparatus according to any one of claims 1, 2 and 4, wherein
- density and/or direction of said magnetic field formed by said magnetic field forming means are adjusted so that said cyclotron resonance effect of electrons becomes larger in a portion within a range from the periphery of said sample to the outer side of the periphery than in the center of said sample, thereby the plasma density being made uniform in positions corresponding to all over the surface of said sample mounting surface.

**IN THE UNITED STATES PATENT AND TRADEMARK OFFICE**

Applicants: T. KAJI, et al.  
Application No.: 10/808,559  
Filed: March 25, 2004  
For: A PLASMA PROCESSING APPARATUS  
Art Unit: 1763  
Examiner: M. Crowell

**DECLARATION UNDER 37 CFR §1.132**

Commissioner for Patents  
P.O. Box 1450  
Alexandria, VA 22313-1450

Sir:

I, **Shinichi Tachi**, do hereby verily declare that:

1. I received the Ph. D. degree in electronic engineering from Osaka University in 1979.

2. From 1979 until 1994 and from 1995 until 2002, I have worked as a member of the Central Research Laboratory, Hitachi, Ltd.

Additionally, I spent and worked for two years from 1994-1995 at headquarters of Hitachi, Ltd., as a planning and marketing officer. As a whole, I worked for 25 years in Hitachi, Ltd.

In addition, I moved to Hitachi High-technologies Co. in 2002 as a deputy general manager of Naka works. I established research and development division there in 2003. I am now an executive officer and general manager of Kasado works

of Hitachi High-technologies Co. The main product, which I have engaged in, is the plasma etching machine.

3. As a member of Scientific/Engineering Societies in the Central Research Laboratory, I had been engaged in developing plasma processing, ion beam technology, ion-solid interaction and semiconductor surface treatments.

Through many activities, I have participated in development of LSI chip processing by collaborating with many semiconductor device industries.

I have been a member of Japan Society of Applied Physics, Institute of Electrical Engineering of Japan, and American Vacuum Society,. and have worked as a committee member of International Dry Process Symposium for these 25 years, and was a chairman in 2003 and 2004.

4. In addition, I have written the following articles in my field:

(1) S. Tachi, M. Izawa, K. Tsujimoto, T. Kure, N. Kofuji, K. Suzuki, R. Hamasaki, and M. Kojima, J. Vac. Soc. Technol. A16, 250 (1998).

(2) S. Tachi, M. Izawa, and M. Kojima, 1997 Dry Process Symp.

(3) M. Izawa, S. Tachi, R. Hamasaki, T. Yoshida, and M. Kojima, 1997 Dry Process Symp.

(4) M. Izawa, K. Yokogawa, S. Yamamoto, N. Negishi, Y. Momonoi, K. Tsujimoto, and S. Tachi, 1999 Dry Process Symp.

(5) Y. Gotoh, T. Kure, and S. Tachi, Jpn. J. Appl. Phys. 32, 3035 (1993).

(11) Masaru Izawa, Shinichi Tachi, and Nobuyuki Negishi, Reaction mechanism in plasma processing., The Vacuum Society of Japan, 2001.

5. I am one of the listed inventors in U.S. Patent Application Serial No. 10/808,559 (hereinafter referred to as "the above identified patent application".) I have carefully read the above-identified application including reviewing the drawings and the claims of the patent application. I have also carefully read the Office Action dated November 17, 2005, as well as USP 5,534,751 to Lenz and USP 5,272,417 to Ohmi.

6. With regard to the above-identified patent application, the specification states on page 40, line 8, et seq., that the discharge confining means, such as indicated by the numeral 37 in Fig. 1, is made of silicon, carbon or SiC. As noted on page 40, line 10 et seq., by virtue of the use of these materials:

"When the discharge confining ring 37 is connected to a high frequency electric power source to cause sputtering by ions, it is possible to decrease attaching of deposits to the ring 37 and also to remove fluorine. "

In each case of using either silicon, carbon or SiC, it is important to note that the material used is free of oxygen (unlike materials such as quartz and silica which both contain oxygen). This avoidance of oxygen is very important in the construction of the discharge confining means, for reasons which will be discussed below. In addition, from further studies of the etching process by me and my co-inventors, we have now determined that making the discharge confining means of silicon has a substantial advantage, not only over materials such as quartz and silica, but also over other materials such as carbon and SiC.

Essentially, our studies have shown that the discharge confining means essentially constitutes a floating electrode during operation of the plasma apparatus. In particular, the discharge confining means has an electric potential on it during the plasma etching operation. As a result, the discharge confining means itself is etched by the plasma. If the discharge confining means contains oxygen, this etching of the discharge confining means will spread the oxygen into the plasma itself, thereby deteriorating plasma and the etching process itself.

In addition to excluding oxygen, we (that is, the inventors) have determined that forming the discharge confining means of the same material as the etched wafer

(specifically silicon) has the advantage that the etching of the discharge confining means itself will have no adverse effects at all on either the plasma or the etched wafer since material other than silicon will not be released into the plasma. Therefore, we have found that silicon is superior not only to materials such as quartz and silica which contain oxygen, but also to materials such as carbon and SiC mentioned as alternatives in the specification, since the etching of these materials will also release materials into the plasma different from the base material of the sample being etched.

With regard to the Lenz Patent, it is noted that column 6, lines 18 through 29 specifically states that the ring assembly 30 which serves as a confinement shield is made of high quality fused silica or quartz. Since both of these materials include oxygen, the Lenz discharge confining means will suffer the above noted problem that, during the etching process, the discharge confining means itself will be etched, thereby releasing oxygen into the plasma. Therefore, the etching of the wafer will be degraded, compared to the superior results which can be achieved using the invention disclosed in the above-identified patent application, specifically, by making the discharge confining means of silicon. In addition, it was noted that the secondary reference to Ohmi noted in the Office Action fails to add anything which would suggest modifying Lenz to make the discharge confining means of silicon, without oxygen.

I further declare that all statements made herein of my own knowledge are true and that all statements made on information and belief are believed to be true; and further that these statements were made with the knowledge that willful false

statements and the like so made are punishable by fine, or imprisonment, or both, under Section 1001 of Title 18 of the United States Code and that such willful false statements may jeopardize the validity of the application or any patent issuing thereon.

**Further Declarant sayeth not.**
